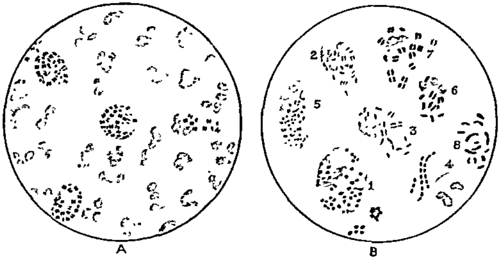
POST-GRADUATE SURGERY

VOLUME III



All represent drawings from gonorrhœal urethral smears, stained by Gram's method (Jensen's modification). Magnification, about 1000 diameters.

A. Shows pus cells containing intra-cellular gonococci, also some lying extra-cellularly. Note that they are Gram negative and kidney shaped.

B. This is a composite painting made up from various urethral smears to show the different varieties of secondary organisms which frequently occur in gonorrhœal pus, more especially in chronic cases. All these secondary organisms may occur within pus and epithelial cells, but more commonly they lie extra-cellularly. Nos. 1 to 6 are painted from the actual specimens. Nos. 7 and 8 are somewhat diagrammatic. Nos. 1, 2, 3 and 5 are the most common types found.

1. Pus cell showing *Staphylococcus albus*—Gram positive. Note that some are lying partially digested in vacuoles and have lost their Gram positive character.
2. Pus cell showing a diphtheroid bacillus (Xerosis type)—Gram positive.
3. Pus cell showing a short Gram positive *Diplobacillus* with pointed ends, indistinguishable morphologically from the *Pneumococcus*.
4. Shows a similar organism to No. 3, except that it occurs in chains, resembling a *Streptopneumococcus*.
5. Shows a small *Diplobacillus*—Gram negative. It assumes various shapes and coccoid forms; the latter are not kidney shaped but lanceolate.
6. Pus cell with a large Gram negative bacillus.
7. Shows the *Diplococcus magnus* of Rosenthal or *Pseudogonococcus*. It is weakly Gram negative, and is four times as large as the *Gonococcus*. It occurs rarely in the urethra, more commonly in conjunctivitis.
8. Shows a diphtheroid bacillus with clubbing and involution forms—Gram positive.

MEDICAL ASPECTS OF SURGERY

by

R. SLEIGH JOHNSON

MEDICAL ASPECTS OF SURGERY

"Surgery is the strongest of all research weapons in the hands of the physician, and posterity, I fear, will not hold us guiltless of the sin of allowing hostility, or imperfect understanding, to grow up between physician and surgeon in this great creative period in the science and the art of medicine. How much more rapid our progress would have been, how much more accurate our labours, what waste of time and effort would have been spared, if, instead of living each inside his own impenetrable ring fence, the physician and surgeon had met on common ground *in the interest of the patient. Our only excuse, the only condonation,* is that the sin was not so much of our own creation as hereditary." (Moynihan, "Essays on Surgical Subjects.")

There *is little need at the present time to stress the interrelationship* and common aim of medicine and surgery. Every surgeon will agree that they are fundamentally inseparable, supplementary the one to the other, and but differing aspects of the same broad general study of disease. It follows, then, that each patient upon whom an operation is contemplated is to be regarded not merely as the possessor of a surgical lesion to be removed or remedied, but as an individual whose other systems merit investigation and assessment of their ability to withstand successfully the surgical measures proposed. It is in evaluation of this "surgical risk" and adoption, where available, of means whereby it may be diminished that the physician can most usefully serve his surgical colleague.

From a still broader standpoint, the risk in operating in a given case is dependent upon other factors besides the physical condition of the patient and the procedure to be carried out, namely, the surgical wisdom, competence and technique of the operator, and the surroundings and facilities under which the operation is to be performed. For the purpose of this survey, the latter factors may be accepted as adequate, and consideration be reserved for the former.

Again speaking generally, operations fall into three groups. In the *first*, the *indications for operation are absolute and beyond question*, as, for example, in perforated duodenal ulcer or strangulated gut, and whatever the patient's condition and circumstances surgery must be attempted as a life-saving measure. Here, *consideration of operative* risk is purely an academic question with no practical influence upon

procedure. The risks, however high, must be taken, in that those of abstension are yet higher or even hopeless.

The *second* group concerns *minor operations* done at a convenient time to surgeon and patient and upon a healthy subject, as, for example, the removal of a lipoma or similar localised condition. In this type the operative risk should be so slight as to be negligible, and therefore one hardly possible or necessary to assess.

It is with the *third or intermediate* group, involving all other cases, that the practical issue is concerned and decision made for or against operation.

This group includes the ordinary type of major operation, carried out not necessarily upon an otherwise fit subject, but in enforced association, perhaps, with other degenerative changes or disease conditions. The patient may, for example, be elderly, obese, or unfit from preceding illness. The choice may be between an operation, which, though desirable from the standpoint of final recovery, cannot be called essential to life and is certainly not free from risk, and, on the other hand, a continuance of medical treatment, with avoidance of immediate danger though with less complete benefit or relief than that afforded by operation if successfully withstood. The gall-bladder, for example, may frequently be the seat of such a choice. An error in judgment may mean an unnecessary death, however good the intention. A great responsibility falls, therefore, upon those charged with assessing the risk and advising as to operative interference.

The factors may now be considered which combine to make a given person either a good or a bad "surgical risk," the latter being defined as one in whom the chances of recovery from operative treatment of his condition fall well below the average.

A. Physiological Considerations

(1) *Age.* The added dangers of operation at the extremes of life are well recognised. Operations, for example, within the first few days of birth, as for congenital deformities, carry a heavy risk, although in later infancy these may be minimised by special care and preparation. Dehydration, hæmorrhage, alkalosis, acidosis, and liability to pulmonary complications are amongst the special dangers in childhood, the risks of these being proportionately greater after abdominal, and particularly intestinal, interference. Speed (but not *haste*) of surgical measures, maintenance of warmth during and after operation, free supply of body fluids and carbohydrates, and suitable choice of anæsthetic combine to keep mortality at a minimum. With regard to the last point, the

use in the main of nitrous oxide-oxygen inhalation, together with local analgesia when indicated, has been found the most useful combination.

Old age similarly has its dangers for surgery, although senile degeneration is to be estimated not so much from years as from objective vascular and other demonstrable changes. Liability to pulmonary events—bronchitis, hypostatic collapse and pneumonia—and to thrombosis of essential arteries is proportionately greater and will need appropriate prophylactic measures. Moreover, the anxieties of middle age, especially as regards continued wage-earning capacity in the hospital patient, are factors increasing surgical risk in the restlessness and economic worry apt to ensue.

The most favourable period for operation is then the intermediate decades, when physique and resistance are good, powers of recovery unimpaired and operative trauma well withstood.

(2) *Sex.* In general, women are better operative risks than men where major surgery is concerned. Liability to shock appears less and resistance to hæmorrhage greater, while pelvic operations in particular are more readily withstood. When possible, it is desirable to avoid the times of menstruation on account of associated metabolic and nervous disturbances. The changes associated with the menopause —nervous, vascular, and endocrine—necessarily carry some increase in general operative risk.

(3) *Physique and bodily conformity.* The unduly thin and the unduly fat are both poor candidates for surgery, the former from lack of nutritional reserve, the latter from mechanical difficulties and impaired resistance. Of the two the fat subject is the greater risk, especially with an abdominal operation. The wound is deep, access to structures restricted, tissues friable and slippery, and differentiation of organs more difficult. Operation-time is thereby prolonged. Fatty infiltration of the heart and pericardium diminishes cardiac reserve, and the added weight of the parietes and fulness of the abdomen hamper the diaphragm. Respiratory complications are correspondingly more frequent. The danger of fat embolism has to be considered; venous thrombosis is commoner; and among late sequelæ ventral hernia is a possibility.

Heavy muscular build may sometimes be a drawback and increase difficulty of approach, e.g. to the kidney, and the lighter, more wiry build is on the whole a lesser risk.

Where operation is not urgent, these risks may be diminished by appropriate dietary measures. The obese are encouraged to reduce weight, and the thin to build up nutrition before the chosen date.

(4) *Habits.* The added risks of the heavy drinker need no emphasis; repeated saturation with alcohol is responsible for his frequent resistance to anæsthetics, while obese build, cardio-vascular degeneration, and hepatic damage carry further dangers. Liability to delirium tremens in the post-operative phase is marked and affords good reason for continuing to give some alcohol throughout this period. The risk of hepatic inadequacy is lessened by the free administration of glucose. Prolonged anæsthesia and diminished resistance to bacterial infection make post-operative pneumonia a complication especially to be feared. Evidence of developed cirrhosis of the liver should be considered a bar to all but essential operations.

The heavy smoker has the scales weighed a little against him as regards irritability of the pharynx and upper respiratory passages and added liability to cough for some days after operation, and it is well for him to cease or at least reduce his smoking for a few days previously.

The drug addict as commonly understood, e.g. the chronic taker of morphia, cocaine or barbiturates, is a subject on whom to avoid operative measures whenever possible. Resistance to anæsthesia and susceptibility to infection and to major mental derangement are marked. When operation is essential, the usual supply of the drug must be continued throughout the period of illness.

(5) *Occupation and social status.* These are to some extent included in the previous considerations. Occupation involving regular exercise and good muscular tone clearly makes for a safer operative risk than the overfeeding of idleness or the coercion of habit and diet associated with particular occupations, such as that of publican, commercial traveller, or some walks of business life. Those subject to constant rush and tear and more than their quota of anxiety are not the best subjects for operation. The added concern when medical men are patients is more than a myth. With this are linked up factors of temperament and emotional type. The phlegmatic is the better risk, being less liable to shock; the apprehensive or nervous type, especially the true neurasthenic, is a poorer risk. He has less faith, less ability to rest and submit to treatment, approaches operation in a mental tumult and often desires in the post-operative stage to direct his own régime instead of leaving it to others. Major mental disturbance, especially of the maniacal form, is not very infrequent after operation in this type, though usually but temporary in duration.

No generalisation can fairly be made as regards racial factors, but these clearly come into consideration with those outlined above.

B. Factors of Previous or Associated Disease

Apart from physiological considerations in assessing chances of recovery from operation, the influence of previous illness or of accompanying defects in other organs or systems than that of the surgical lesion in question must naturally be considered. The effect on the surgical risk will, of course, vary with their nature and severity. *A complete examination will alone reveal such associated conditions*, especially if they be latent before operation, as with some pulmonary lesions. A convenient method of review of the main systems concerned will be on an anatomical basis:

(1) *Cardio-vascular disease.*

Of associated medical conditions, one of the chief to arouse doubt in the mind of the surgeon as to operability is the presence of known or suspected heart disease, although anxiety is frequently greater than need be. It is without question a sound procedure that every patient *prior to operation should be critically examined as to his cardio*vascular system, but limitation of this survey to the customary stethoscopic examination immediately before anæsthesia is of negligible value and is to be strongly condemned. To be of real help in decision, investigation must be made on a definite plan.

The patient is first interrogated for history of previous cardiac illness, and for symptoms pointing to myocardial weakness; of these the most important is inquiry for undue dyspnœa on exertion, with an estimate of the degree of effort needed to produce it, whether this be walking on the level, on an incline or upstairs, or only strenuous hurrying. *Alternatively, dyspnœa may be of nocturnal or "cardiac asthma"* type. In the same way, inquiry is made as to precordial or substernal pain, with its degree, if present, from tightness or discomfort to true anginal features. If the patient's condition allows, an estimate of exercise tolerance should be made to assess the cardiac reserve; if this be satisfactory, the pulse-rate should return to its resting level usually within one, and certainly within two, minutes.

On examination of the heart, the points to be noted are the size of the heart, the rate and rhythm, the presence of valvular lesions and the tone of the myocardium. The latter will be indicated by the force of the impulse, together with the length and pitch of the first sound at the apex. Signs of ill omen are a diffuse cardiac impulse and a short high-pitched or reduplicated first sound, with tic-tac or gallop rhythm. The need for accurate interpretation of cardiac murmurs, organic or

functional, need not be stressed. Estimation of the pulse and the condition of the arteries, and recording of the systolic and diastolic blood-pressure, should always be made. Cyanosis or distension of veins is noted, and search made of the extremities, lung bases and sacrum for œdema, and for signs of passive congestion of abdominal organs. Where the circumstances will allow, and especially where doubt is aroused by clinical examination, an electrocardiographic record and an orthodiagram or teleradiogram of the heart should be made. Evidence of myocardial damage, not patent on ordinary clinical tests, may by these means not infrequently be revealed, and warning be given against the advisability of operation.

With these data, and bearing in mind the nature of the operation proposed, the surgical risk may be reasonably assessed. For purposes of discussion, the following simple classification may be adopted :

(a) *Rheumatic heart disease.* Acute rheumatic carditis, as with any other actively toxic condition of the heart muscle, is a bar to operation involving general anæsthesia. Perhaps one of the most frequent errors is the too-early removal of tonsils, with recrudescence of endocarditis and joint inflammation. Chronic rheumatic heart disease, however, when well compensated and where the tone of the heart muscle is good, carries little if any added risk, especially in adolescence and early adult life. The mere presence of a valvular lesion need not be feared so long as the patient has no symptoms of undue dyspnœa or fatigue and shows no signs of congestive failure. An essential operation is never contra-indicated, and seldom one of choice, while selection of anæsthetic is not greatly affected. Where time allows, benefit may accrue from a preliminary period of rest in bed before operation, and where the patient is nervous on account of his heart simple sedatives will save the unnecessary work of the heart resulting from emotional tachycardia. There is no call for digitalis in the absence of failure. Similarly it is wise that convalescence should not be hastened. Of the slightly greater risks associated with rheumatic valvular lesions, in particular with mitral stenosis, perhaps the most important, though unavoidable when it occurs, is an added liability to post-operative embolism—arterial from blood clot in the left auricle, or venous from stagnation in the great veins. Pulmonary infection and hæmorrhagic infarction are also somewhat more common.

The presence of cardiac failure, however, radically alters the prognosis. Wherever possible, operation upon patients with cardiac œdema or gross signs of congestive failure should be avoided, or at

least delayed until the maximum of compensation is restored by adequate rest in bed and digitalisation.

Abnormalities of rhythm are of importance in this respect. Occasional premature beats may be disregarded in the absence of more definite contra-indications. Their occurrence during anæsthesia is in any event very common. Auricular fibrillation in rheumatic cases, if well controlled by digitalis and unaccompanied by failure, carries no great risk and should not deter from operation ; it is essential to give adequate preliminary treatment so as to bring the ventricular rate within normal limits. Auricular flutter likewise calls for preliminary digitalisation. Liability to attacks of paroxysmal tachycardia should be a warning feature, since a prolonged attack during or after operation might well be terminal. Attempt should be made, where the liability is known, to control or abolish the attacks by quinidine in the pre-operative period. The value of an electrocardiogram in interpreting such irregularities is clear.

(*b*) *Arteriosclerotic and degenerative heart disease.* In this wide group the risks of surgery are far greater. The patient is usually older, and there is fault with the vital myocardium rather than any mechanical valvular difficulty. Where examination points to a widespread degeneration of the heart muscle and presumptive interference with its own blood supply, any non-urgent or non-essential operation is to be avoided. Alternatively, where there is no other choice, special care and precautions are to be adopted. Decision is often made easier by the circumstance that many operations at this age are of the latter type, and the risks although great are legitimate.

Syphilitic heart disease with aortitis, aneurysm or aortic regurgitation, in contrast to the rheumatic group, is a bad risk. Sudden death, during or shortly after operation, is not uncommon, hence only essential surgery should be performed in such cases. Similarly, patients with angina pectoris, signs of coronary atheroma, or previous coronary infarction are undesirable subjects for elective surgery. The factors must be weighed of the urgency of operation against the degree of dyspnœa, fatigue or chest pain present. Some disorders of rhythm and action, such as heart block or pulsus alternans, indicate profound exhaustion of the heart muscle and diminished reserve, and the risk is then so great as to permit of imperative operation only. The presence of acute coronary disease (apt to be confused with some acute abdominal lesions such as cholecystitis) is an absolute bar to operation.

With regard to hypertension, a persistently raised diastolic pressure is of more adverse significance than a corresponding rise of systolic

the added rise of pressure produced. With nitrous oxide, cyanosis and venous congestion are to be avoided; with ether, so great a concentration as would irritate the respiratory passages.

Similar care is needed in the stage of recovery from operation. Mental rest and relief of pain are important in their reflection upon the heart's action. Convalescence must not be hastened, as it is usually found that the cardiac reserve is to some degree lessened by a major operation.

In assessing cardiac risk, the need must not be overlooked of simultaneous investigation of correlated systems, such as the renal or hepatic, for adequacy of function.

(2) *Respiratory affections.*

As with the heart, the respiratory tract can never safely be omitted from a review of operative risk. The question of pulmonary complications having already been considered in some detail (see Vol. II, page 2001), only a brief outline of the main factors concerned need be given.

Failure of recovery from operation through a respiratory disaster is most often brought about by the development of an intercurrent broncho-pneumonia; less often pulmonary suppuration is the cause, and occasionally a severe embolism. In some circumstances, the possibility of these dangers may be recognised beforehand from a knowledge of preceding or accompanying pulmonary disorder or other predisposing factors. These may lead to postponement or avoidance of non-urgent operation, or to adoption of special precautions in anæsthesia and post-operative conduct of the case. Factors adversely influencing surgical risk from the pulmonary aspect include the following:

(*a*) *Age.* There is a special liability in the very young and in the aged to bronchial and pulmonary infection. Maintenance of body warmth is the best safeguard.

(*b*) *Habitus.* Obesity is an added liability, in virtue of its mechanical burden upon respiration, with impaired mobility of the diaphragm and ineffectiveness of cough.

(*c*) *Previous respiratory affection.* No patient with a common cold or active bronchitis should be operated upon except in emergency. The risk is definite and neglect may be serious. Anæsthesia is less well borne, danger of downward spread of infection to the lungs not inconsiderable, and the strain of coughing may cause stitches to burst or hæmatomata to form, and in any case rest and recovery are impaired by the pain and discomfort produced. When operation is essential, irritant anæsthetics are to be avoided.

The patient with asthma and chronic bronchitis, usually with associated emphysema, should, where possible, be operated upon in the summer rather than the winter months to diminish the chances of superadded infection. Where feasible, preliminary respiratory exercises and massage, aimed at mobilising the thoracic cage and improving diaphragmatic excursion, will repay the patient in lessening his handicap and the risk of post-operative chest troubles. Severe emphysema may be an indication for local or spinal anæsthesia.

As regards operative technique, the insertion of additional supporting sutures in such subjects is a wise precaution, together with their retention for an added period to minimise the risk of their yielding from cough. Post-operative care will include the use of suitable stimulating expectorants and the avoidance of depressing drugs; atropine especially is of prophylactic and therapeutic value.

Reactivity of latent phthisis after operation is still a cause of disappointment, or worse, as regards the final result. Where suspicion is aroused from the previous history, skiagrams of the lungs will indicate need for suitable anæsthesia if operation is still desired. Inhalation anæsthesia may be replaced by basal narcosis or spinal analgesia, or irritant vapours at least avoided. Similar precautions will be required in the presence of chronic non-tuberculous lung disease, such as pulmonary fibrosis or bronchiectasis, where this complicates, say, an abdominal case.

(*d*) *Nature of proposed operation.* The nearer the site of operation to the diaphragm, as with a high abdominal section, the greater the risk of pulmonary sequelæ from trauma and inhibition of its movement. Thus pulmonary collapse and broncho-pneumonia occur most frequently after such operations as cholecystectomy or gastrectomy. The need is evident, therefore, for avoidance of unnecessary bruising or stretching of tissues, and for promoting free basal expansion in the post-operative stage. In this respect carbon dioxide is the most valuable stimulant to respiration available, while mechanical restraint from bandaging must be minimised.

(*e*) *Aspiration of infective material.* Inhalation of contaminated secretions under anæsthesia is the chief cause of post-operative abscess of the lung, and a contributory cause of broncho-pneumonia. Any obviously septic lesion in the mouth or throat, such as infected teeth or tonsils, should, wherever possible, receive attention and be eradicated before a major operation is performed. When the operation field is itself in the region of the upper respiratory tract, blood or infective material must be prevented from entering the bronchi by means of

suitable posture of the patient, and by the adaptation of anæsthesia to include removal of all local secretions by mechanical suction.

The above considerations apply to the risks of general surgery from thoracic complications. A review of the subject would be incomplete without mentioning another aspect, namely, the question of operative risk as applied to thoracic surgery itself. Perhaps this generalisation may be allowed—that if thoracic surgery is to make its legitimate progress and to keep pace, say, with the advances of abdominal surgery, then risks must be expected and braved in this developing stage of its history. The possibilities of surgery have recently been directed to a number of formerly incurable medical conditions of the chest, such as unilateral bronchiectasis or fibrotic phthisis with persistent cavitation, and some cases of pulmonary new growth, and by well-designed thoracoplastic or lobectomy operations dramatic cures have ensued. In such established states the outlook from medical treatment is so poor and life so restricted that it is justifiable to take the risk, assuming that the case conforms to certain requirements. It is reasonable, moreover, to expect that with further advances in surgical and anæsthetic technique these risks, now admittedly great in many instances, will be progressively lessened. Such aids as the oxygen-tent are already not without effect.

Medicine and surgery in chest diseases are rapidly becoming more and more complementary to one another. Thoracoscopy, division of adhesions, bronchoscopic diagnosis and therapy, adaptations of technique for empyema treatment, all instance the close interrelation of medicine and surgery in this sphere.

C. Risk from the Renal Aspect

Turning attention from the chest to the abdomen, the state of the kidneys as regards functional efficiency must pass the surgeon's survey, both from the general aspect and more particularly where a genito-urinary operation is contemplated. The simplest observations, nevertheless of great value, are made from a careful examination of the urine, noting especially the amount passed, specific gravity, and presence of albumen, pus cells, red blood cells or casts. This examination, which should be an invariable routine before any operation, would at once exclude from the danger of elective surgery cases of active nephritis or gross urinary infection.

In gross renal disease the operative risk is high, and the means available to reduce it are but meagre. In acute nephritis any operative procedure is undesirable, since the degree of renal damage is thereby

sure to be further increased. A word of caution is needed here, as with acute rheumatic infection, against the too hasty removal of tonsils after acute inflammation, or a vigorous or extensive eradication of septic foci, dental or otherwise, procedures liable to be followed by diffuse or focal inflammation of the kidney in its attempt to excrete organisms or their toxins swept into the blood stream at operation.

Chronic parenchymatous nephritis constitutes a risk so grave that wherever possible alternative means of treatment to operation should be adopted. Renal œdema and susceptibility to infection go hand in hand, and acute pericarditis, pleurisy or pneumonia is a not unlikely sequel, if the other danger of anarsarca and suppression of urine is escaped.

Chronic interstitial nephritis is a less serious risk, the dangers in marked cases being from uræmia or from vascular accident such as cerebral hæmorrhage.

Where operation must be performed in spite of the handicap of nephritis, the renal function must be improved as far as possible by adequate rest, removal of toxic contributory causes, restriction of protein intake, giving of alkalis and liberal fluids (apart from œdema), and free excretion by the bowel.

Operation on one kidney, e.g. for calculi, demands, first of all, separate investigation of the function of both kidneys, as by collection of ureteric specimens of urine, cystoscopic inspection of the passage of special dyes from each ureteric orifice, or X-ray examination after injection of radiologically opaque substances (e.g. uroselectan-B) excreted by the kidney. One sound kidney is adequate to withstand any ordinary surgical risk; a previous nephrectomy for accidental injury, for example, need not be considered a bar, such is the normal renal reserve.

Cases of enlarged prostate with retention of varying degree, upon whom operation is contemplated, need perhaps the greatest care in determining as far as possible the renal reserve. How meagre at best are the available methods is well recognised, and linked up with the vast normal reserve of the organ. The urea-concentration test is on this account of little value. Estimation of the blood urea is of somewhat greater reliability, though still capable, by an apparently normal result, of giving a misleading prognosis in some cases. A figure above 40 mg. per 100 cc. indicates some renal damage, while above 60 mg. the surgical risk of a one-stage operation is high, and preliminary bladder drainage indicated. The most satisfactory test available is estimation of the Blood Urea Clearance (Van Slyke), any reading below 60 per cent

of normal signifying damaged renal function and carrying with it a poor surgical risk (see Vol. I, page 135).

The value of the much-neglected ophthalmoscopic examination of renal cases may be mentioned. The presence of albuminuric retinitis *may indicate more clearly than any chemical test an impending uræmia.* As already pointed out, the cardio-vascular system cannot be divorced from the renal and must be simultaneously investigated.

A few points are worthy of consideration relating to medical aspects of primarily surgical conditions of the renal system. In connection with genito-urinary tuberculosis, the frequency should be borne in mind with which these lesions are secondary to pulmonary tuberculosis, and an X-ray examination of the chest never omitted, even in the absence of physical signs. Both as regards anæsthetic precautions and possible tuberculin treatment, this investigation is of value. In the former case lighting up of disease may follow ether inhalation; in the latter *a great risk is present of an acute allergic flare of activity in* the lungs, and tuberculin injections should be sedulously avoided.

In any condition of apparent unilateral hydronephrosis the possibility is to be remembered of its being in fact a congenital cystic disease of the kidney confined in the early stages, as is not very uncommon, to one organ only. The symptoms in polycystic disease are those of chronic interstitial nephritis, as are the urinary and cardio-vascular changes. Removal of the one kidney will but shorten the resistance of the other, should this subsequently become affected.

Chronic cystitis or pyelitis, under-explained from the surgical aspect, should always cause attention to be directed to the nervous system, *to exclude its being a trophic lesion associated with spinal* cord disease, such as tabes dorsalis, myelitis or disseminated sclerosis. A similar cause may account for obscure bladder pain, strangury, and delayed or precipitant micturition.

A point of difficulty sometimes met with in differential diagnosis is worthy of note. Renal embolism in medical conditions is apt to be confused with renal colic, each being associated with shock, sudden pain in the loin, and hæmaturia. Investigation of the heart will indicate the source of infarction. The not uncommon occurrence of renal pain and hæmaturia from passage of oxalates is another source of confusion, and an inquiry as to the taking of strawberries, rhubarb, spinach or tomatoes may give the clue in diagnosis.

D. Surgery of the Biliary System

If renal function is difficult to determine, hepatic function is doubly so. The known tests have on occasion failed to demonstrate damage when post-mortem examination has revealed, for example, replacement of two-thirds of the organ by growth.

The clinical condition is the best guide where the safety or otherwise of operation is at issue. Chemical tests of the urine for bile-salts and pigments and for urobilin may, if required, be supplemented by examination of the blood for its *Van den Bergh Reaction and Icterus* Index. The ability of the liver to store lævulose and galactose may be determined, together with its capacity to eliminate special dyes by the biliary passages, cholecystography being a special application of this method. Finally, where desired, the secretion of the liver may be directly examined by duodenal intubation.

The main risks to the surgeon arise in conditions of obstructive jaundice, when the hepatic metabolism is upset by damming-up of the liver cells with bile. Other conditions where operation is dangerous include cirrhosis of the liver, with portal obstruction and its accompanying venous stagnation and ascites, and states of toxic hepatitis, whether from drugs, chemical poisons or infection.

The risks of jaundice are chiefly two-fold, namely, hæmorrhage and post-operative acidosis or cholæmia, described in a previous section (see Vol. I, page 748). Estimation of coagulation-time of the blood gives some index of the former risk.

Chronic obstructive jaundice is of itself an indication for surgery when it may by such means be relieved, so great is the danger of liver failure if obstruction be allowed to remain. Preliminary treatment will be dietetic, by restriction of fats and giving of abundant bland fluids and glucose, with cholagogues and saline aperients, simple diuretics and alkalis. Glucose may, if desired, be given by the bowel, or intravenously in 5 to 10 per cent solution in saline, while its rapid utilisation is aided by giving 10 to 20 units of insulin at the same time. The danger of hæmorrhage at operation is lessened by administration of citrates in full doses for a few days previously, with injections of calcium gluconate, while a pre-operative blood-transfusion is also of value. Shock is common with liver damage, owing to the reduced ability of the organ to detoxify the histamine-like substances produced by trauma, and intravenous injection of 6 per cent gum saline may help to counteract its effects. The choice of anæsthetic must be that least toxic to the liver cells and least disturbing to their carbohydrate metabolism,

preferably ether or gas and oxygen in conjunction with a local anæsthetic.

The gall-bladder is an organ of both medical and surgical interest. From the medical standpoint it is probably one of the most frequently overlooked foci of general intoxication. Its affections are, moreover, not always easy to diagnose from thoracic disease. The ease with which the pain of chronic cholecystitis may be mistaken for angina deserves special recognition, while the reverse is also true in that an apparent biliary colic may, in fact, originate from coronary infarction. The liability of a tender, congested liver being interpreted in error as chronic cholecystitis may also be mentioned.

There is, moreover, a special tendency for chronic infections of the gall-bladder to bring about a toxic degeneration of the heart muscle. Care of the heart in gall-bladder operations is thus particularly indicated.

With regard to cirrhosis of the liver, the need for its exclusion is evident before any operation is carried out for hæmorrhoids or hæmatemesis. Treatment, moreover, of ascites from this cause by short-circuit operations is seldom a justifiable undertaking. The risks of infection, portal thrombosis and cholæmia are grave.

E. Metabolic Disturbances: Diabetes Mellitus

The surgical risks peculiar to the diabetic subject are of two kinds. In the first place, there is in this disease a special liability to a group of complications of surgical significance, dependent upon a combination of vascular or trophic disturbance with metabolic upset. These include gangrene, skin sepsis, trophic ulcers, and cataract, each of which needs appropriate modifications of treatment.

The second group concerns the added risk of diabetes as it affects general abdominal or major surgery. This has already been reviewed *in a previous section (see Vol. I, page 790), and a brief summary will* therefore suffice. Whereas prior to the discovery of insulin the dangers of surgery were maximal, it may now fairly be said that, given reasonable facilities and time for pre-operative treatment, the additional risk is slight.

The principle in operations of choice is that the patient should, by generous feeding and liberal use of insulin, be got into the best physical condition to withstand operation, with carbohydrate metabolism so balanced that no glycosuria or acidosis is present and the blood sugar is at a normal level. Any preliminary septic factor is treated where possible.

Immediately before operation is carried out, an adequate reserve of sugar in the liver is ensured by giving glucose and insulin in appropriate amounts, continuing the same care in the post-operative phase, controlled throughout by blood-sugar and urine tests. Operative trauma is reduced to a minimum and a suitable choice of anæsthetic made, commonly gas and oxygen, with basal, spinal or local anæsthesia also if desired. Special watch is made for hypoglycæmia in the recovery stage.

Acute abdominal (or other) surgical emergency in the diabetic produces more profound disturbance of metabolism—perhaps coma, and the dangers and difficulties of treatment are correspondingly increased. Diagnosis itself may be obscured. Necessary surgery is not to be shirked or postponed, even in the presence of coma. The principles of conduct of the case are essentially as outlined above, except that far larger doses of insulin and glucose are required. It is also no less important to give abundant fluids, in order to counteract previous dehydration.

F. Endocrine Disorders

(1) *Surgical aspects of hyperthyroidism.* Whether or not in toxic goitre the primary disturbance is within the thyroid gland, the most successful means of treatment available still remains a partial thyroidectomy. The proportion of established cases permanently restored to health by medical treatment alone is small, and the recent trend of opinion is to refer an increasing number of cases to the surgeon, and at an earlier stage of illness. The risks of permanent cardiac incapacity from thyrotoxicosis and the dangers of operating on the desperately advanced case are both thereby avoided. Milder cases may not, however, require the aid of surgery, and decision where and when to operate is an eminently suitable circumstance for consultation between physician and surgeon.

The previously high mortality of thyroidectomy has been greatly reduced by careful choice of case, preliminary medical treatment, suitable premedication and anæsthesia, and skilful operative technique, the death-rate being now as low as 1 per cent in competent hands. Every thyrotoxic patient should first pass through the physician's hands. Before operation is decided upon, complete rest in bed should be enforced for at least a month, and contributory sepsis as in teeth or tonsils eradicated. The maximum of mental and physical rest is obtained with the help of sedatives such as bromide and luminal, and an attempt is made to improve the patient's nutrition by

dietary measures. If, as is not infrequently the case, auricular fibrillation is present, digitalis is given in sufficient amount to control the irregularity, larger doses often being needed than those customarily adequate in non-toxic fibrillation. An estimation of the basal metabolic rate at progressive stages of treatment affords one of the most valuable guides to improvement.

Where the results of preliminary rest and medical treatment point to the need for surgical intervention, the B.M.R., for example, remaining above 50 per cent of normal, the patient is given iodine by mouth to produce a *phase of remission optimum for surgery*. The giving of Lugol's iodine (5 per cent iodine with 7·5 per cent pot. iodide in distilled water) in doses of 5 minims t.d.s. in milk, for a period of two to three weeks, ensures the maximum of remission. This is the correct use of iodine in toxic goitre, and not indiscriminate dosing for months or years *on end. On the day prior to operation, and on the subsequent two days*, double this dosage is given by mouth.

Apprehension on the part of the patient is minimised by basal premedication, while the most satisfactory anæsthetic is gas and oxygen combined with local infiltration of novocaine. Immediately after operation one drachm of Lugol's solution is given per rectum in a glucose-saline enema and repeated at intervals as may seem necessary.

Occasionally, operation is followed by an acute thyrotoxic crisis, shown by restlessness, delirium, rising temperature, extreme tachycardia, and sometimes vomiting and diarrhœa. In these circumstances, drachm doses of Lugol's solution may be repeated six-hourly by the rectum, or in emergency 20 minims of the solution given intravenously at the same interval, diluted in 10 cc. of saline or given with a 5 per cent glucose-saline infusion. Rapidly acting cardiac stimulants such as coramine, with digitalin, may be required, and full doses of sedatives; if bromide and chloral hydrate are inadequate, morphia should be given without hesitation.

After the operative phase, iodine by mouth should be continued for two to three months in the form of Lugol's solution, 5 minims twice daily. A spontaneous return of the fibrillating heart to normal rhythm is frequent; if necessary, quinidine may be given. Abnormal rhythm is never a contra-indication to surgical treatment, nor even heart failure if due primarily to the goitre.

Consideration of the thyroid gland in its relation to medicine and surgery would be incomplete without reference to the value, in some cases of gross congestive heart failure unresponsive to medical treatment, of total removal of the thyroid gland. The lowering of basal

metabolism so obtained gives the circulation in such cases a further chance of improvement.

(2) *Other endocrine disturbances.* With other endocrine glands questions of medicine and surgery overlap to a much less extent. Suprarenal tumours may masquerade as medical cases and come under observation for obesity or hirsutism, while removable tumours of the pituitary are generally first seen by the physician. In both instances, *although the risk is high, operation is the correct advice.*

Tetany sometimes occurs after operation for removal of a parathyroid tumour, and treatment consists in administration of parathyroid extract and of calcium salts by intravenous injection.

Unexplained surgical death is sometimes attributed to status lymphaticus and the blame placed upon a supposed thymic disturbance; the significance or otherwise of such deductions is reviewed on page 4257.

G. Medical Considerations in Gastric Surgery

No attempt is made here to review this vast and interesting subject. In no section of therapeutics is a greater co-operation to be desired between physician and surgeon. One would make the general plea, in these days of rapid change, for peptic ulcer still to be regarded as a medical disease, in which surgical co-operation is to be desired in well-defined circumstances. While not doubting the successful progress of gastric surgery, every case should nevertheless be given the opportunity of an adequate trial of medical treatment in the first instance. Failure of such medical treatment to make the patient's life bearable, doubt as to malignancy, or the occurrence of special complications *may then all severally justify surgical intervention.* (See also Vol. I, page 297.)

The value and place of histidine in the treatment of peptic ulcer awaits further trial, but the results so far have proved disappointing.

A second plea is for torrential hæmatemesis to be treated invariably by medical rather than by surgical means. Operation at such a stage of illness is fraught with danger.

In evaluating the operative risk in any given case of chronic peptic ulcer, the factors to be borne in mind are the duration, position, size, and fixity of the ulcer, and any doubt present as to its possible malignancy. The general condition of the patient is a further deciding factor, and should always be improved as much as possible before operation is undertaken. Special knowledge of gastric surgery, skill in technique and care in anæsthesia frequently determine the issue.

in hæmorrhagic purpura is usually followed by recrudescence, perhaps with fatal hæmorrhage—a further reason against delay.

(4) *Other conditions with splenomegaly. Gaucher's disease* in infants has sometimes been treated by splenectomy, but the late results are disappointing, as shown by Pick and Maingot. In other conditions associated with enlargement of the spleen and blood changes, including leukæmia, pernicious anæmia, and lymphadenoma, no lasting benefit has been shown to accrue from removal of the spleen. In doubtful cases of glandular enlargement, surgical biopsy of a gland may, however, be of great value.

In conclusion, and reviewing the question of surgical risk as a whole, the lesson of history must not be forgotten. Fifty years ago it was generally fatal to open the abdomen. A craniotomy for cerebral tumour provided a short-cut to the post-mortem room. Now recovery has followed the removal of the entire stomach, the whole of one lung, or an entire lobe of the brain. Although, alas, we are told by some that *surgical technique has reached its zenith of achievement, it is,* however, scarcely conceivable that either surgical or anæsthetic skill has attained a stage no longer consistent with further progress.

Incisional Hernia

HERNIA

CHAPTER I

Introduction

A hernia is the displacement of an organ from the cavity in which it is normally contained through an opening in the walls of that cavity. For the present purpose herniation of the abdominal contents only will be considered, and discussion will be limited to the more common and important varieties. The opening through which a hernia occurs is usually either a natural foramen or channel through which blood-vessels or other structures leave the abdomen, or the site of some injury. Thus the common sites are the inguinal and crural canals, the umbilicus, and the scars of operations. Under conditions, however, in which prolonged or repeated increase of abdominal pressure coincides with general wasting, almost any of the fibrous junctions in the abdominal wall may give way. Such anomalous herniæ may be found in the very old and debilitated inmates of public institutions, who throw the strain of constant coughing on abdominal walls shrunken to paper thinness; in such it is not uncommon to find four distinct herniæ in each groin, protrusions through the linea semilunaris and under Poupart's ligament lateral to the femoral artery, in addition to the more common inguinal and femoral ones.

A patient will sometimes present himself with a large hernia which has clearly been in existence for a considerable time, but which has only been noticed accidentally by him within the last few days. Another will say that he has known of the swelling for several years but it has given him no trouble whatever, and he has only sought advice because his employers insisted on it or his friends advised it. Usually, however, some disability is occasioned from the start. But in any case, whether the hernia is causing trouble or not, when a surgeon discovers it, he is bound to advise control or cure, that is, some retentive or protective apparatus or an operation. For no hernia left to itself will undergo cure, remain stationary, or even be tolerable for any length of time. The hernia itself is the result of abdominal pressure acting on a weak spot, and abdominal pressure is a constant force, maintaining the position of the viscera, keeping up the flow of blood in the great veins, and aiding the return of the diaphragm after its descent. It is increased

to expel the contents of the abdominal or thoracic viscera, or to fix the trunk as a base for the limbs—that is, in vomiting, micturition, defæcation, parturition, coughing, or muscular work. With this force constantly acting, any hernia is bound to increase in size, while the hernia in turn will tend to inhibit and interfere with abdominal movements and give a feeling of insecurity during any strenuous exertion. To these disabilities is added the danger of strangulation, present at all times in some herniæ, but only appearing later in others. No hernia, therefore, may safely be disregarded, and some form of treatment should be insisted upon as soon as the diagnosis is certain.

Because it is inherent in human nature to avoid any course of action which involves risk, pain, or loss of time, a great many patients will wish first to discuss the question of a truss. The brilliant results of operative repair in herniæ of moderate size are sufficiently well known to-day to induce the majority of young and active men to demand surgery, but on the other side are the skilfully worded advertisements of those who claim to "build up the tissues" by simple apparatus, so that very often the surgeon is called upon to state simply the pros and cons of treatment by apparatus. In very general terms it may be said that apparatus is not curative but merely retentive, and must therefore be worn permanently, not merely all the patient's life, but at all times of the day and night. It is therefore irksome to an extent that varies with the sensibility of the patient, the type and strength of the apparatus that he requires, the nature of his work, and the delicacy of his skin. It is only effective if it is made exactly, worn constantly, kept in repair, and renewed when weak. It is more effective in some type of herniæ than others, but in all it is liable to produce some degree of pressure atrophy in the tissues upon which it rests, and therefore to become less effective with time. On those general grounds alone, the adoption of apparatus should be strongly discouraged in the young and healthy.

Two particular questions are often asked: "Can a truss cure a hernia?" and "Can a truss retain a hernia, prevent it enlarging, and allow work in reasonable comfort and without the risk of strangulation?"

Cure is possible in the inguinal or umbilical herniæ of infants, but in these alone. A congenital inguinal hernia is due to persistence, in whole or in part, of the processus funicularis or the canal of Nuck, diverticula from the cœlomic cavity which normally remain patent till just before birth. Their persistence after this somewhat arbitrary date is evidence of delay, but not necessarily of failure in the process of

obliteration, which may still take place naturally some weeks or even months later if allowed to do so. For such a natural cure it is necessary that the sac should be, and remain, empty. A truss must, therefore, be worn continually day and night for the first year. If the hernia comes down during this trial period, any possibility of closure is probably lost, and if it appears after the end of a year when the truss has been left off, it is highly improbable that natural closure can then take place.

An infantile umbilical hernia is an acquired defect, due to stretching of the newly formed cicatrix. If protrusion of abdominal contents is prevented by a suitable binder and pad, the scar tissue will contract once more and become strong, and a natural cure will result. Such a cure may confidently be expected by the end of six months in the great majority, but may take place up to eighteen months. After this time it is, however, unlikely.

It is theoretically possible that the prolonged wearing of a truss might bring about the natural cure of an *oblique inguinal hernia*, even in adult life, by the formation of adhesions between the walls of the sac at its neck obliterating the internal ring. It is, however, excessively unlikely that such adhesions would occur exactly at the ring or that they would completely obliterate the lumen. They are usually between the sac wall and its contents, and not at the commencement of the sac, but half an inch or so further down, where its walls are pressed together by the pad; further, they are usually bands or partial adhesions. Such attempts at repair have no value in preventing the entry of the abdominal contents into the sac, but rather favour strangulation when they do come down.

The *second question*, whether a truss can retain a hernia with comfort and safety, can only be answered with regard to particular herniæ.

OBLIQUE INGUINAL HERNIA

If the hernia is an early one, that is, whatever its size, if the neck is small, the internal ring neither stretched nor displaced inwards, and the muscles good; in other words, if the hernia, when reduced with the patient standing, will not come down again unless he coughs, strains, or walks about, it can be retained with certainty by a well-fitting truss against any but the most violent straining efforts. On the other hand, this type of hernia is usually seen in young healthy men, and is one for whose cure only a simple type of operation is necessary, and in which a permanent cure is almost certain. In proportion as the hernia is old, the internal ring enlarged, the muscles weak, or the patient's occupation strenuous a truss will be less effective. *The continual wearing of*

a truss over an oblique inguinal hernia tends in time to produce atrophy of the inguinal muscles, thickening of the sac near the internal ring, and adhesions between the sac and its coverings and contents. Such changes have two results. Abdominal contents coming down into a hernia pressed on by a truss are much more likely to become strangulated than where no truss has been worn; and an operation when it is required cannot rely upon simple removal of the sac, but must include some plastic manœuvre to strengthen the inguinal canal.

DIRECT INGUINAL HERNIA

A direct hernia, unless it is really large, is particularly suitable for a truss. It appears late in life, it tends to enlarge very slowly, and it can be retained by the simple backward pressure of a pad, and when so retained will not increase appreciably over many years. The sac is wide-mouthed, and there is no tendency for adhesions to form in or around it, or for contents to be trapped in it. It will be found that many seamen and general labourers are able to carry out their strenuous callings wearing double inguinal trusses for direct hernia without any appreciable loss of efficiency. Here, then, a truss is effective and safe. Operative repair, on the other hand, implies some fairly elaborate method of reconstruction, whose permanent success cannot be assured with complete certainty.

FEMORAL HERNIA

While in inguinal hernia a truss is usually effective, and is merely discountenanced in many cases because it is unwise, in femoral hernia it should only be recommended for most exceptional reasons. The hawker of patent apparatus will shout his ability to cure all femoral herniæ; the instrument maker is always ready to make a femoral truss. But a survey of the anatomical factors concerned will throw considerable doubt upon the efficiency of any mechanism to control such a hernia. The inguinal canal belongs to the trunk, and a well-made truss embracing the pelvis will lie securely during all movements, and maintain an even pressure on the weak spot. The femoral canal is in the thigh, and all movements at the hip must necessarily displace a pad lying over the saphenous opening and attached to a spring or girdle encircling the trunk. Even were it possible to maintain even and continuous pressure on the crural canal (as it would be, for instance, in a patient with an ankylosed hip-joint) such pressure would only be effective on the fundus of the sac and the distal half of the canal. The neck of the sac and the abdominal end of the canal lie behind and

above Poupart's ligament, where any pressure, short of that which will rupture Poupart's ligament and obstruct the femoral vein, is powerless *to prevent the entry of abdominal contents into the hernia.* The potential dangers of a femoral hernia are far greater than those of any other type. Strangulation is commoner, progresses more rapidly to gangrene, and is more fatal in its outcome. A truss should never be ordered, or countenanced if the patient suggests it, except in those rare wide-mouthed and easily reducible swellings, where the age or health of the patient prohibits an operation even under local anæsthesia.

UMBILICAL HERNIA

In the umbilical herniæ of infants, a belt with a pad, or even a home-made retentive apparatus of strapping, will usually retain the protrusion, and will effect a cure by the end of the first year in the majority of cases. Here the abdominal wall is normal and unstretched right up to the edge of the orifice, there is little subcutaneous fat, and the pad will remain in position over the opening and keep the sac empty. In adults the state of things is usually different. The whole abdominal wall is sagging, the linea alba stretched, the hernial orifice a somewhat indefinite opening lying beneath a thick layer of subcutaneous fat, the sac loculated, and the contents usually reducible in part only, if at all. It is difficult to maintain a pad in the correct position or to apply its pressure to the ring, and even if the hernia can be reduced and kept back, it will slip past the pad with any extra exertion or sudden movement of the abdominal wall. Because of the liability of these herniæ to strangulate, and the high mortality of the complication, a truss should only be advised for small and completely reducible swellings where the risk of operative repair is considered prohibitive.

INCISIONAL HERNIA

The efficacy of a belt depends entirely upon the size and character of the hernia. A wide bulge involving the whole scar can usually be retained well by a belt alone, or by a belt with a pad over the protrusion; it will not increase in size, and the belt will allow a fairly normal life and a considerable degree of exertion. When, on the other hand, the sac has a large fundus, with a narrow neck passing through a small aperture in rigid scar tissue, control by any form of pad is uncertain, and strangulation, on account of the deficiency in the peritoneal lining and the many adhesions, is extremely likely.

THE PLACE OF APPARATUS IN THE TREATMENT OF HERNIA

The foregoing remarks may be summed up as follows:

(1) *A truss should be ordered:*

(*a*) *As a possible method of cure* in all inguinal and umbilical herniæ of infants during the first year of life. Operation should only be undertaken during this period for progressive increase in size in spite of conscientious use of the truss by the mother; for inability to wear the truss owing to skin soreness or other reasons; or for threatened complications.

(*b*) *To prevent increase in size and avert the risk of strangulation* in a case where operation will be undertaken at a later date. In inguinal and umbilical herniæ of infants from the end of the first year (after which a cure can no longer be expected) till the earliest suitable age for operation (in my opinion four years for inguinal, two years for umbilical hernia). In oblique hernia in adults, when operation is advised, but postponed for social or economic reasons, or on account of general or local disease.

(*c*) *As a safeguard after an emergency or limited operation,* which cannot be regarded as a radical cure. In many operations undertaken for strangulation, or in the aged for threatened strangulation, the sac is removed, but the measures that would appear necessary to render the canal proof against yielding in the future have not been carried out because of the condition of the patient. In such cases a truss with quite light pressure is usually sufficient to prevent a recurrence.

(*d*) *As the only possible safeguard* in all *reducible* herniæ when operation is out of the question.

(2) *A truss may be permitted* in most direct inguinal and many incisional herniæ, and in oblique inguinal hernia where the patient is a poor operative risk.

(3) *A truss should be discouraged* in oblique inguinal hernia if the patient is healthy.

(4) *A truss is dangerous* in femoral herniæ, in the umbilical herniæ of adults, and in incisional herniæ with a small rigid opening and a large sac.

GENERAL PRINCIPLES IN THE OPERATIVE REPAIR OF HERNIA

The basic principles of hernia surgery are simple—the removal of the sac at its neck, and the closure of the hernial canal at its commencement. Of these two demands the second is the more important. There may be no sac, the sac may have no neck, or it may be so short and wide that its removal is unnecessary; but, except in certain instances, secure closure of the hernial orifice is an indispensable step without which the removal of the sac is of no more than temporary value.

The chief exception is an oblique inguinal hernia with a congenital sac into which contents have only recently and occasionally descended. In such there is no "hernial canal" or "hernial orifice" in the sense of an abnormal opening. The internal inguinal ring is a normal aperture and only becomes abnormal when it is stretched. In a hernia of the type under discussion the only abnormality is in the structures passing through the ring; there should be vas, vessels and nerves only, but in such a case there is, in addition, a collapsed peritoneal pouch. If the pouch is entirely removed, all abnormality is removed with it, and the inguinal region becomes normal.

In all other cases, however, the opening is an abnormal one, which must be securely closed after removal of the sac. The method required for closure will depend upon the size of the opening and the nature and power of repair in the tissues which bound it. In some cases the tissues in the neighbourhood, drawn together by absorbable sutures, will provide satisfactory repair; in others, some such closure must be reinforced by drawing down adjacent tissues or turning in flaps from structures in the neighbourhood: in others, free transplants of living connective tissue from some other part of the body may be used to repair the defect; in others again, unabsorbable foreign material may be used. The principles alone of these different methods can be discussed here; their detailed application must be left to the consideration of individual herniæ.

In most surgical operations catgut is used to-day for all deep sutures. Its value is that when its work is done it is entirely absorbed, leaving nothing but living tissues at the site of operation. It must be remembered, however, that the work of catgut, indeed of all sutures, is one of approximation only. No sutures, even unabsorbable ones, can keep tissues together against tension tending to separate them, for more than a short time. In the face of continued tension, sutures, if not absorbed, will cut out, and the parts will return to their original site unless they are fixed by the permanent agency of living connective

tissue. Thus there is little value in the stouter sizes of catgut; indeed, in this material size is little indication of strength. In my experience No. 0 and even No. 00 is usually as strong as No. 1, and the sizes above No. 1 are often weaker and more unreliable than the finer ones. Moreover, catgut, though it can be absorbed, is a material not received kindly by tissues. It produces considerable reaction, as any surgeon who has been obliged to reopen a wound for any purpose during the first ten days after suture will have been able to ascertain for himself. In the presence of infection, it resists absorption, and prolongs local sepsis till it is discharged.

Kangaroo tendon provides an absorbable suture material of greater strength than catgut. While this strength gives it a place in bone surgery, it is very doubtful, for the reasons given above, whether the parts concerned in hernia repair should ever be subjected to a tension which cannot be exerted by sutures of No. 1 catgut. In my opinion the bulk of kangaroo tendon, and the insecurity of knots made with it, prohibit its use for this class of work.

The use of free transplants of connective tissue is old in surgery, but the investigation of factors concerned in their successful application, and the development of a satisfactory technique, is the work of Gallie. He showed that connective tissues, when transplanted free to another part of the body under aseptic conditions, remain alive, and after undergoing a transient inflammatory reaction, regain their original microscopic appearance. Thereafter they remain unchanged, retaining their strength and structure indefinitely. They become united to their surroundings by fibrous tissue. If this is abundant, as when the edges of the transplant and its bed are scarified or when non-absorbable sutures are used, the union will be firm; if the connective tissue is small in amount and subjected to strain, the union between the graft and its bed will become stretched. By using strips of fascia woven into the receiving tissues instead of patches stitched to them, the graft becomes incorporated with its bed by a living union and displacement is impossible.

Gallie sutures are usually taken from the fascia lata on the outer side of the thigh. The original technique is to make an incision about 12 inches long down to the fascia lata, reflect the superficial fascia backwards and forwards for the requisite distance, and cut parallel strips ¼-inch wide from the fascia. When the gap following removal is not much over an inch wide, it may be closed with interrupted stitches of catgut. If, however, the edges can only be got to meet with considerable tension they should be left unclosed. Direct exposure of the fascia is

time-consuming, and occasions a certain loss of blood. By transferring this part of the operation to an assistant, who cuts the strips while the surgeon prepares the hernia, and closes the thigh while he inserts them, both disadvantages are minimised, but a large scar remains in any case. Instruments whereby the strips can be cut through small transverse

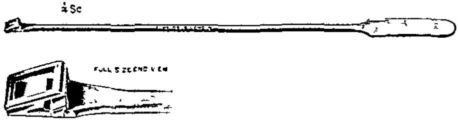

Fig. 1981.—Small's fasciatome.

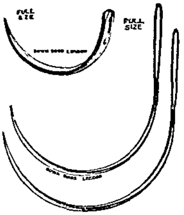
incisions at either end of the ilio-tibial band are the most obvious solution. The difficulty to be overcome is that, unless the fascia is cleared of other tissues on both its surfaces, it will not separate easily into neat parallel strips. The early fasciatomes used to bring out ragged irregular wisps with fat and muscle adhering; modern ones, of which Small's (fig. 1981) is an excellent example, are entirely satisfactory. Clean regular fascial sutures of full length can thus be cut with a minimum of trauma, and open exposure will only be used when the

Fig 1982.—Needles for fascial suture.
(*Top*) Gallie's.
(*Bottom*) Lane's.



surgeon is not provided with the apparatus, or when he wishes to get the maximum number of strips from one limb, or one or more of extra width. There is, of course, no particular merit in the fibres of the ilio-tibial band, beyond their length and number. For limited operations, suitable aponeurotic strips may *often be cut from tissues in the* immediate neighbourhood of the operative field. In the repair of inguinal herniæ such strips may often be obtained from the external oblique aponeurosis. The fascial strips are used with special needles. Gallie's (fig. 1982) are flat needles with a half-circle curve and a wide eye to take the suture; Lane's are of lesser diameter, the eye being replaced

by a wire loop. One end of the suture is passed through the eye and tied over itself with fine silk; the free end is similarly tied with silk to prevent splitting. "In taking the first stitch the needle is passed through a tough portion of the edge of the gap to be closed and then through the terminal end of the suture (fig. 1983). In this way a slip-knot is produced which forms an excellent anchor. The suture is woven strongly into the edges with as many bites as seem necessary, and passed backwards and forwards across the opening until its whole length is used up. Owing to the slippery character of the fascia it will be found useful to anchor the sutures at every second or third stitch by some form of

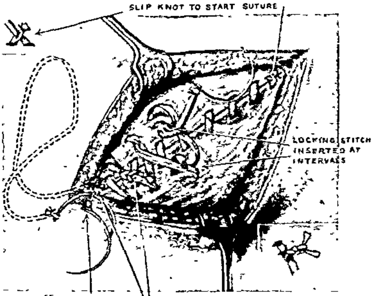


FIG. 1983.—TO ILLUSTRATE THE METHODS OF FASCIAL SUTURE.

knot (fig. 1983). We usually combine a single loop-knot with transfixion. When the first suture has been used up a second may be attached to it in the same way as pieces of tennis gut are fastened together, and the sewing continued. In this way one suture after another may be inserted until the opening is completely closed. The suture is finally ended by splitting its terminal portion into two strands which are tied together about the suture in a triple knot. This knot should be made secure by transfixing it with a catgut ligature which will hold its loops in contact until they become firmly healed together."

While fascial suture will solve most of the problems that can possibly confront the surgeon in the way of repair, it must be remembered that fascia lata, or any aponeurosis transmitting the pull of a muscle, is

strong only in the direction of that pull. Its longitudinal fibres are held together by very few transverse ones, and large patches, even when securely anchored all round, are quite unfitted to take a strain applied equally to all their margins. The body, however, possesses in the derma a connective tissue sheet of almost unlimited size and strength, a felt-work of tough interlacing fibres equally strong in all directions. We use derma to sole our boots, cover our saddles, drive our machinery; paraphrased, one of the oldest sayings runs "there's nothing like derma." Rehn of Freiburg has shown the many uses to which dermal transplants may be put, among others for reconstructing the capsules

2 A graft of the required size is cut from the derma
3. The Thiersch flap is stitched back over the defect

of joints and repairing really large defects in the abdominal wall which may follow severe sepsis in operation scars, or the excision of large areas for malignant disease.

A dermal transplant should be cut the size of the defect to be covered. After the defect has been defined, a template may be cut in sterile jaconet. With a skin-graft razor, of which Humby's pattern is the most reliable when large areas are concerned, a Thiersch graft, somewhat longer than the dermal patch required, is cut from the outer side of the thigh, but left hinged at one end (fig. 1984). The jaconet template is applied to the denuded derma, and the required patch cut round and dissected off with some underlying fat. The Thiersch flap is laid back on the raw surface which remains, retained in position with three or four marginal stitches, and pressed down with a firm dressing. The dermal patch is transferred to the defect, the fatty layer towards

the surface, the superficial layer downwards, being stitched in position with interrupted sutures of silk, or fascial strips. Being to some extent elastic it will overlap the margins of the defect all round, and afford a wide area by which it will adhere to the underlying tissues.

Many unabsorbable materials have been used from time to time in the repair of hernia, but the majority are of no more than historic value. Two only merit discussion at the present time—silver-wire used in the form of a filigree, and silk. The silver-wire filigree can be obtained in any size or strength, and may easily be made by the surgeon himself, from materials that are everywhere available, to suit the needs of a particular operation. It is easily sterilised, is usually well tolerated by the tissues, and becomes in time incorporated in a dense web of fibrous tissue of which it forms a strong framework. The disadvantage of such a filigree is that it is rigid and therefore cannot move with parts which, in all herniæ, are subjected to movement. It is true that in the great majority of cases such rigidity causes no recognisable trouble. But, like all unabsorbable materials, silver-wire will, in the presence of infection, whether present when it is inserted or arriving later by the blood stream at the site of operation, keep up the infection indefinitely. The damage which a rigid material may cause among moving tissues makes such infection commoner with wire than with silk. Sepsis will persist till the foreign body is removed or eliminated; but whereas silk under such circumstances can be discharged piecemeal through a very small sinus, a silver-wire filigree can only come out as a whole. Till this happens it will lie in an abscess-cavity, and may cause serious or even fatal damage by eroding a large vessel or a loop of intestine. *In my opinion the perfection of modern* methods which depend upon the use of fascial or silk sutures or large dermal transplants has left no place for the filigree. It must be admitted, however, that some surgeons are very satisfied with the method to-day. Any who consider that the use of a filigree may solve some problem in the repair of hernia with which they are faced would do well to consult the article by Laurie McGavin in the first edition of Choyce's *System of Surgery*, Vol. II, Chapter II.

Silk is used much more widely as a suture material on the continent of Europe than in England and America. Yet it has very much to recommend it. It is more pliable and more than twice as strong as catgut of the same diameter. It knots securely; silk ligatures may be cut " on the knot," whereas catgut must be cut two or three millimetres beyond the knot, which even then will often come undone if subjected to intermittent strain. *Because of its security, fine silk is employed by*

many surgeons for the ligature of vascular structures subjected to constant movement—notably in thyroid work. Silk, again, is received by the tissues much more kindly than catgut, producing no appreciable reaction. For this reason it is used almost universally in the exacting technique of neuro-surgery. In common with all unabsorbable foreign materials, it will keep up any infection which is present when it is introduced. Silk should never be applied to any operation where infection is feared, as in those on herniæ where the skin is sore from the pressure of a truss, or excoriated in the folds of a pendulous groin. When it is used, special care should be exercised in the arrest of hæmorrhage and the obliteration of dead spaces in the wound during closure, to prevent any blood-borne infection of the tissues later. With these precautions silk will be found an excellent servant in hernia surgery. Should infection supervene, silk does not aggravate it, but merely prevents the healing of the wound. Once an opening has appeared, it settles down to a small sinus with none of the signs of inflammation, and through this the silk is quietly and painlessly extruded, having usually in the meantime done the work for which it was inserted.

Fascial sutures and silk compete for the surgeon's patronage when he desires to bridge a weak area with a firm sheet of connective tissue which cannot yield. Fascial suture may appear to the scientific surgeon to have a sounder claim. The material is an autogenous transplant, which retains its strength and microscopic structure unimpaired, and which is woven into the tissues and becomes incorporated by living bands into their substance, which when so incorporated becomes part of them and therefore shares their resistance to later infection. The practical operator, who is forced to admit that even the teaching of experimental animal surgery must be correlated with clinical experience, will also remember disadvantages. Fascial suture always adds an operation on the leg to one on the hernia ; it adds its time and severity, and almost prohibits the use of local anæsthesia. In post-operative infection fascial strips will slough like any other suture material. Perhaps the most obvious disadvantage is the size of the sutures themselves, which must be $\frac{1}{4}$-inch in diameter. These strips, and the coarse needles required to carry them, make a sorry mess of the delicate structures of the inguinal canal, particularly Poupart's ligament, which is very easily separated thereby into disconnected longitudinal strips. While admittedly no harm appears to result in most cases, the job is not one to please the surgeon whose ideal is atraumatic surgery. In my own opinion fascial suture is excellent for the repair of tendons, ligaments, and the capsules of joints, and of those abdominal defects whose margins are scar tissue

or felted aponeuroses—namely, umbilical or incisional herniæ. Where any such plastic reconstruction is required in the inguinal and femoral canals, I very much prefer silk, used in the same manner as fascial strips—that is, as a protecting lattice work and not as an approximating suture.

I always use Pearsall's No. 4 Chinese twist silk. This is boiled for ten minutes with the instruments, and the length to be used is put in $\frac{1}{1000}$ flavine solution till it is required. Some surgeons prefer silk in paraffin ; because I wish the fibroblasts to work freely between the fibres of the silk, and because paraffin is known to give rise to granulomata and occasionally to sarcomata, I never use this preparation.

CHAPTER II

Inguinal Hernia

THE INGUINAL CANAL

The post-graduate student is already familiar with the anatomy of the inguinal region, and it is only proposed to discuss here those points which have a bearing on the principles or technical details of the operations which will be discussed later.

The inguinal canal lies above the inner half of Poupart's ligament. The skin is smooth over the outer part, hairy towards the pubis, and at the level of the pubic spine has the rugose surface and large sebaceous glands of the scrotum and labium majus. The superficial fascia shows the layers of Camper and Scarpa; the latter, which is attached to the fascia lata of the thigh, must be divided with the knife before the femoral opening can be explored through an inguinal incision. A well-marked and constant flexure crease caused by the flexion of the trunk and thighs, and called by the old anatomists the line of Venus, is seen in this region. It crosses the mid-line at the hypogastrium about $1\frac{1}{2}$ inches above the pubis, and on each side it curves upwards as it passes out, crossing the line of Poupart's ligament in its outer fourth, and fading away on the outer side of the thigh just below the anterior superior spine (fig. 1985). I personally prefer to use this crease for the incision in all operations for inguinal and femoral hernia.

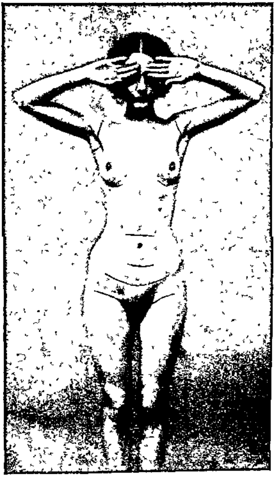

Fig 1985.—Flexion creases on the trunk of the normal adult.

It will rightly be urged that cosmetic surgery has no place in the pudendal region. But a good scar is more than a matter of appearance; it is a guarantee of comfort to the patient, and an aid to the surgeon who may have to operate again in the same region. The standard inguinal incision leaves a scar which is rarely sightly, sometimes keloid, and occasionally painful; these drawbacks are partly the result of its direction being in the line of tension of the skin, instead of in the line of rest as is a crease incision, and partly due to its encroachment at the lower end on skin that is sterilised with difficulty. In children the crease incision, by removing the stitches and dressings a further $\frac{3}{4}$-inch from the area of soiling, has very real advantages.

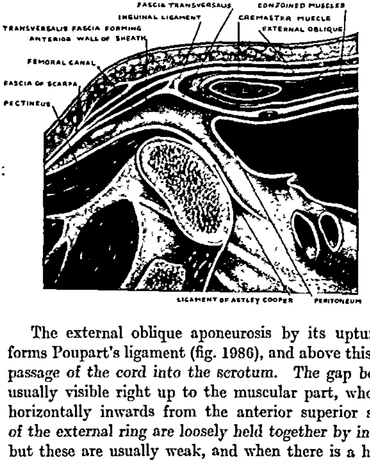

Fig. 1986.—Sagittal section passing through the inguinal and femoral canals, modified from a special dissection by Mr. J. Whillis. (The most important modification is that the cremasteric layer has been shown as muscle instead of fascia.)

The external oblique aponeurosis by its upturned lower border forms Poupart's ligament (fig. 1986), and above this splits to allow the passage of the cord into the scrotum. The gap between its fibres is usually visible right up to the muscular part, whose margin extends horizontally inwards from the anterior superior spine. The pillars of the external ring are loosely held together by intercolumnar fibres, but these are usually weak, and when there is a hernia in the canal, both they and the less obvious transverse fibres holding the aponeurosis together higher up are stretched. For this reason I have always disliked those methods of approach to the inguinal canal which make a point of leaving the external ring untouched. I believe that opening of the ring by dividing the intercolumnar fibres is necessary, not only for atraumatic reflection of the cremaster afterwards, but also to allow

the stretched ring to be sutured back to its normal size. Medially the external oblique aponeurosis joins the anterior rectus sheath, but it does so a full inch inside the outer border of the rectus muscle, so that for this width the sheath is formed by contributions from the internal oblique and transversalis only. The internal oblique springs from the outer half of Poupart's ligament, the transversalis from its outer third. Both muscles fuse to form the conjoined tendon, which arches over the cord to be inserted into the pubic crest and inner inch of the ilio-pectineal line. The cremaster arises from the inner half of Poupart's ligament and the lower border of the internal oblique, and descends over the cord as far as the testicle in the form of loops. Such is the text-book description. In practice these three muscles appear to form one system, through which the descending testis has thrust its way, carrying an abundant covering of muscle-fibres with it. The internal oblique and transversalis cannot be recognised as separate structures where they adjoin the inguinal canal, the conjoined tendon is not tendinous, and it is impossible to say where the lower border of this structure lies or where the cremaster begins. The differing origin of the two deeper muscles from Poupart's ligament appears merely as an overlaying of the cord as it emerges from the internal ring by their more superficial fibres. The cremaster is that part of the system which sweeps over the cord rather than gains insertion into the pelvis. If the conjoined tendon is unduly elaborated by descriptive writers, the cremaster receives insufficient attention. When this is carefully reflected in the inguinal canal of a healthy young man, it is found to be a well-developed muscle nearly $\frac{1}{8}$-inch in thickness which completely surrounds the cord (fig. 1986), not merely covering, but intervening between it and the fibrous posterior wall of the canal. The posterior wall of the inguinal canal is again a more real structure than text-book descriptions allow us to imagine. The transversalis fascia, elsewhere a thin membrane, is here a tough sheet which is firmly attached to Poupart's ligament and the ilio-pectineal line. Superficial to the fascia is a continuous sheet of muscle, the conjoined tendon medially, the posterior fibres of the cremaster laterally. The internal ring itself is no descriptive figment, but a strong fibrous opening in the fascial sheet, which in the undamaged canal has well-marked margins of considerable strength. On its medial side the deep epigastric artery forms a landmark, but is of no structural importance.

These anatomical points are all of importance when we come to consider the normal defences of the inguinal canal and the principles of repair when they have become effete. Any sub-division of the posterior

testis; the effaced segment can usually be traced as a fibrous band uniting the fundus of the sac to the summit of the tunica vaginalis. The retro-funicular and intra-funicular herniæ, grouped together as infantile, are of more uncertain origin. The explanation which is usually given in text-books, and the least likely, is that the funicular process is closed at the internal ring, remaining patent distally, and that an acquired sac is later pushed down behind it or into its lumen. Every stage intermediate between the funicular and retro-funicular varieties is met with, the tunica vaginalis extending up into the inguinal canal for varying distances in front of the sac, so that the infantile varieties are probably due to irregularities in the descent or obliteration of the

vas deferens, from which it can be separated only with difficulty. In herniæ associated with imperfectly descended testes, this sheathing of the cord by the sac is so intimate as to render separation and closure of the peritoneal process a matter of real difficulty. The sac bears further traces of its congenital origin in numerous bands of fibrous, muscular, and nerve tissue which streak its outer surface, and in the occasional presence of small rests of adrenal cortex in its walls. In most cases the process of peritoneum is a simple tube. Occasionally the distal part is divided by septa into a series of compartments, which may be distended with fluid; incomplete septa and diverticula from the main channel are also found. These irregularities are in most cases of developmental origin, but they may be the result of pressure by a truss.

The extra-peritoneal fat usually ceases at the internal ring, and in the operation for hernia its appearance is an indication that the ring has been reached. The fat may, however, invade the cord, particularly in the inguinal canal of adults. Two conditions are seen: In one the fat extends down the cord distinct from the vessels and sac as a lobulated finger-like process carrying an obvious blood-vessel with it; in the other the fat is invaginated into the neck of the sac, and bears, when seen from the inside of its cavity, a very striking resemblance to a loop of small intestine protruding through the opening.

A direct hernia is merely a bulging of the posterior wall of the inguinal canal. This portion of the abdominal wall, when viewed from the inside, has been sub-divided artificially by Hesselbach's triangle, but this nomenclature is of no direct interest to the surgeon and of no particular significance. The portion which yields first is that which is formed by the transversalis fascia alone, that is, the part medial to the epigastric artery, below the arched fibres of the conjoined muscle, and lateral to their insertion into the ilio-pectineal line. The bulge is a general one, roughly hemispherical in shape, and the sac, which hardly merits such a name, has no obvious neck. It is covered by fascia throughout. As the hernia enlarges, it spreads upwards and outwards. The epigastric artery becomes arched over it, and in a larger hernia may appear to separate the swelling into a bilobed one. The lower fibres of the conjoined muscle and the cremaster become stretched, and the external aponeurosis becomes thinned. A direct hernia does not come through the external ring in the sense that an indirect one does, but when increasing in size it finds less resistance in the intercolumnar fibres than in the more fully developed parts of the aponeurosis, and may well

testis; the effaced segment can usually be traced as a fibrous band uniting the fundus of the sac to the summit of the tunica vaginalis. The retro-funicular and intra-funicular herniæ, grouped together as infantile, are of more uncertain origin. The explanation which is usually given in text-books, and the least likely, is that the funicular process is closed at the internal ring, remaining patent distally, and that an acquired sac is later pushed down behind it or into its lumen. Every stage intermediate between the funicular and retro-funicular varieties is met with, the tunica vaginalis extending up into the inguinal canal for varying distances in front of the sac, so that the infantile varieties are probably due to irregularities in the descent or obliteration of the

funicular process, and have no acquired element. The distinction is of academic interest only, and affects neither the diagnosis nor the treatment of these herniæ, unless the possible confusion of an inexperienced surgeon on finding two serous cavities be taken into account.

The testicle is formed in the lumbar region, descends during fœtal life behind the peritoneum of the posterior abdominal wall and iliac fossa to the internal ring, and then traverses the abdominal wall, taking its vessels with it and maintaining the same relationship to the peritoneum which has preceded it into the scrotum. The sac of a congenital hernia therefore lies in front of the cord, or rather surrounds it in front, above, and below, so that in transverse section it shows as a horseshoe-shaped slit into which the cord is invaginated, much as the testicle appears to be [illegible] into the tunica vaginalis. The sac is [illegible] to [illegible] of the cord, and particularly to the

vas deferens, from which it can be separated only with difficulty. In herniæ associated with imperfectly descended testes, this sheathing of the cord by the sac is so intimate as to render separation and closure of the peritoneal process a matter of real difficulty. The sac bears further traces of its congenital origin in numerous bands of fibrous, muscular, and nerve tissue which streak its outer surface, and in the occasional presence of small rests of adrenal cortex in its walls. In most cases the process of peritoneum is a simple tube. Occasionally the distal part is divided by septa into a series of compartments, which may be distended with fluid; incomplete septa and diverticula from the main channel are also found. These irregularities are in most cases of developmental origin, but they may be the result of pressure by a truss.

The extra-peritoneal fat usually ceases at the internal ring, and in the operation for hernia its appearance is an indication that the ring has been reached. The fat may, however, invade the cord, particularly in the inguinal canal of adults. Two conditions are seen: In one the fat extends down the cord distinct from the vessels and sac as a lobulated finger-like process carrying an obvious blood-vessel with it; in the other the fat is invaginated into the neck of the sac, and bears, when seen from the inside of its cavity, a very striking resemblance to a loop of small intestine protruding through the opening.

A direct hernia is merely a bulging of the posterior wall of the inguinal canal. This portion of the abdominal wall, when viewed from the inside, has been sub-divided artificially by Hesselbach's triangle, but this nomenclature is of no direct interest to the surgeon and of no particular significance. The portion which yields first is that which is formed by the transversalis fascia alone, that is, the part medial to the epigastric artery, below the arched fibres of the conjoined muscle, and lateral to their insertion into the ilio-pectineal line. The bulge is a general one, roughly hemispherical in shape, and the sac, which hardly merits such a name, has no obvious neck. It is covered by fascia throughout. As the hernia enlarges, it spreads upwards and outwards. The epigastric artery becomes arched over it, and in a larger hernia may appear to separate the swelling into a bilobed one. The lower fibres of the conjoined muscle and the cremaster become stretched, and the external aponeurosis becomes thinned. A direct hernia does not come through the external ring in the sense that an indirect one does, but when increasing in size it finds less resistance in the intercolumnar fibres than in the more fully developed parts of the aponeurosis, and may well

bulge through this without, however, reaching the scrotum. While any classification of types of direct hernia is unnecessary, it is advisable to point out that a rare variety, unmentioned in text-books, is occasionally encountered in which the posterior wall of the inguinal canal medial to the deep epigastric artery shows a small circular deficiency with firm, almost tendinous margins, through which a tubular process of peritoneum, indistinguishable on clinical examination from an indirect inguinal hernia, escapes and often emerges through the external ring. Whether such a hernia is of congenital origin, due to some trauma, or caused by a localised extra-peritoneal lipoma which weakens the fibrous sheet at one spot. is undetermined.

The sac of any inguinal hernia, as it enlarges, tends to draw further peritoneum from that lining the abdominal parietes into its walls, and with the peritoneum any mobile intra-abdominal structure which it clothes. Thus the bladder may be drawn into the neck of the sac on the inner side, the cæcum into the posterior wall of a right hernia, and the iliac colon into a left one.

THE DIAGNOSIS OF INGUINAL HERNIA

Any detailed account of the methods of clinical investigation of the inguinal canals would be out of place in a book addressed to post-graduate students, who may be presumed to have had considerable experience in the examination of patients before they come to study the details of operative surgery. Inspection should never be omitted, for a small hernia is often better seen than felt; this is particularly true of bubonocele in women and small children, where in a small sac the overlying fat often obscures the impulse on coughing; inspection, too, is often the most certain method of distinguishing a definite hernia from the common condition of bulging groin seen in feeble and sedentary men, where the whole inguinal region seems to come forward against the hands when the patient coughs.

The differentiation between an indirect and a direct hernia is often difficult, and sometimes impossible. It is not of major importance, for the type of large wide-mouthed hernia in which distinction is hard usually needs an operation, one which involves some form of plastic repair of the canal, and the exact relations of the swelling will therefore become apparent when the tissues are exposed. Direct herniæ are usually seen in men over forty: they are bilateral and symmetrical in size and position. A hernia which appears as soon as the patient stands without any straining effort, and which disappears as soon as he lies down without any pressure applied, or which, when reduced, returns

immediately, is probably direct; one whose length exceeds its breadth, or which comes anywhere below Poupart's ligament or medial to the pubic spine, is probably oblique.

The differential diagnosis between inguinal hernia and other inguino-scrotal swellings again seldom arises. Ordinary common sense will serve to distinguish swellings superficial to the abdominal wall, such as enlargement or abscess of the inguinal glands, or those deep to it, in the psoas or iliac vessels, from swellings in the inguinal canal proper. These must arise from some structure in the spermatic cord, and are either tumours—lipoma or fibromyoma—or varicoceles, or abnormalities in the mechanism of testicular descent—retained testes or hydroceles of the cord. A lipoma is softer than a hernia and gives no impulse on coughing, but unless accompanied by a sac, it rarely attains sufficient size or gives trouble enough to attract the attention of the patient. A fibromyoma forms a firm rounded swelling, which can only be distinguished with certainty from an encysted hydrocele by the absence of translucency. A varicocele can never be mistaken for anything else, unless one of the varices has ruptured.

A public schoolboy was seized with sudden pain in the left groin during a game of Rugby football, and was carried off the field and taken to the school sanatorium. A rounded swelling occupying the inguinal canal and extending through the external ring into the scrotum was found by the school doctor; it was tender, irreducible, gave no impulse on coughing, and was not translucent. A strangulated inguinal hernia was suspected, but as the boy complained of no abdominal pain and his bowels were opened by an enema, he was merely kept in bed and the pulse recorded every four hours. By next morning the left half of the scrotum was black, and it was clear that the swelling was a hæmatoma inside the infundibuliform fascia.

An encysted hydrocele of the cord is more often diagnosed than seen. The true encysted hydrocele is a small rounded translucent swelling, sharply demarcated at both ends, which is seldom encountered after the age of puberty. The majority of rounded translucent swellings in the inguinal canal are encysted hydrocles of a hernial sac, whose neck has become blocked by a plug of omentum; examination of the neighbourhood of the internal ring, where the cord is found to be thickened, will reveal their true nature.

LOCAL ANÆSTHESIA FOR HERNIA

The method of local anæsthesia is nowhere more valuable than in the surgery of hernia. Here operation must on occasion be undertaken for pain, increase of size in spite of a truss, irreducibility or threatened strangulation, in patients whose age or general condition would

prohibit such a step, were it not for the certain and greater risk of the imminent complication. Most of the risks are eliminated by a local anæsthetic; bleeding is minimal, and time sufficient for the most elaborate plastic procedures, should they be required, is afforded to the surgeon.

The nerves which must be blocked for an operation on the inguinal canal are many: The skin of the groin is supplied by branches of the 12th dorsal, 1st lumbar, external cutaneous and genito-crural nerves, that of the scrotum by the ilio-inguinal, scrotal branches of the internal pudic, and the long pudendal from the small sciatic; the abdominal muscles and peritoneum are innervated by the ilio-inguinal and ilio-hypogastric nerves, and the cord and testis receive their sensation from

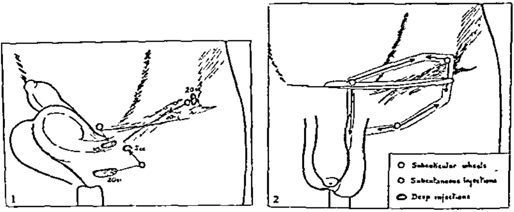

Fig. 1988.—LOCAL ANÆSTHESIA FOR INGUINAL HERNIA. (For details see text.)

the spermatic nerves accompanying the vessels. The plan outlined may be relied upon to give complete anæsthesia lasting for two hours.

The solution recommended is:

Novocaine	1 %
Quin. and Urea Hydrochloride	¼ %
Adrenalin $\frac{1}{1000}$	1 drop to 10 cc.
Normal saline to required amount.	

Three subcutaneous wheals are raised with a fine needle, one a finger's-breadth medial to the anterior superior spine, one over the saphenous opening, and one over the suprapubic skin crease in the mid-line (fig. 1988). A 3½-inch needle is inserted vertical to the skin through the first wheal, and 20 cc. are injected into the muscles, the point of the needle being pushed down during injection till it strikes bone; this injection will block the ilio-inguinal, ilio-hypogastric and last dorsal nerves. The needle is then withdrawn from the muscles, and pushed again through the external oblique aponeurosis, and a further 10 cc. are

injected deep to the aponeurosis in a direction towards the pubis. The needle is next inserted through the second wheal, and 20 cc. of solution are injected along the base of the scrotum which is held up, to block the scrotal nerves. Withdrawn slightly, its point is then pushed to the pubic spine, and 5 cc. are injected here. Through the third wheal a line of subcutaneous injection, 15 to 20 cc. in all, is put in along the skin crease, extending an inch across the mid-line and outwards to beyond the anterior superior spine. Still using the same wheal, 10 cc. are injected into the cord, which is held up for the purpose. Lastly, a continuous line of subcutaneous injection, using about 40 cc. in all, is placed around the whole area, uniting all three wheals, and passing from that in the mid-line beside the penis and down the mid-plane of the scrotum. If the injection is made before the surgeon puts on his gown and gloves for the operation, complete anæsthesia will be assured by the time he is ready.

THE GENERAL PRINCIPLES OF OPERATION UPON INGUINAL HERNIA

Any surgeon who attempts a survey of the literature of inguinal hernia approaches an almost impossible task, for very few men appear able to pass from qualification to retirement without describing a new operation for the cure of this condition. In a work intended to assist the post-graduate student, the writer must confine himself to an account of what he considers to be the essential principles of surgical treatment, and must accept responsibility for the selection of those principles. An analysis of the cure statistics from different clinics is likewise impossible without taking up much more space than the value of such an analysis would justify. In general it may be said that close upon 100 per cent of cures should be expected after operations upon inguinal hernia in children, about 95 per cent after operations upon oblique inguinal hernia in adults, and about 90 per cent after operations upon direct hernia. It is often stated that the commonest reason for recurrence is sepsis in the wound; but surely no surgeon of experience is convinced by this statement? Sepsis enforces prolonged rest and calls forth an abundant reaction of repair; induced sepsis was the basis of the mediæval treatment by blistering and is probably the modus operandi of the "modern" treatment by injection. Could it be controlled, it would be the reparative surgeon's best friend. It is common experience, in any case, that the majority of the recurrences encountered lie under beautiful linear scars. In the writer's opinion, failure is usually due to the operation being done by the wrong surgeon or by the wrong method. The anatomy of the inguinal canal is more

complex than that of any other part of the abdominal wall, and the repair of its defects calls for far greater skill than does the closure of a laparotomy wound. Yet hernia operations are rarely considered important. They are lightly undertaken by men who are not surgeons at all, and who refrain from attempting any other abdominal procedures. In hospitals they are often regarded as introductory exercises for the novice, and are left by the chief to his assistant when he has finished the more interesting part of his list. It is well known that even enormous and old-standing herniæ can be cured by an appropriate method skilfully performed; does it not follow then that when a simple hernia recurs the operation for its cure has either been inappropriate or imperfectly done? Chief among such technical reasons for recurrence are failure to remove the sac at its neck, failure to close the canal at its commencement, and damage to the natural safeguards of the canal. The neck of the sac and the opening in the transversalis fascia which constitutes the internal ring lie under cover of the origin of the internal oblique muscle, and they are not seen, much less efficiently treated, in any method which does not include full exposure of the inguinal canal and retraction of the internal oblique; yet exposure and ligature of the sac through the external ring, or through a small incision over the middle third of the canal, is still recommended in text-books and practised by some surgeons. The writer's views upon the mechanism of the inguinal canal have been set forth in the section upon anatomy and physiology. The reader who accepts these, must also accept their corollary, that any damage to the muscular sphincteric mechanism of the canal, that is, to the conjoined muscle and cremaster, will not merely invite recurrence, but ensure it. Bassini first inculcated the importance of the exposure of the whole inguinal canal and isolation of the sac from the other structures of the cord right up to its neck, and so paved the way for better technique. His name deserves to be placed with that of all great leaders. But the measures he advocated for closure of the canal when the sac had been removed are a useless mutilation of beneficent structures that can only be excused by the date of their introduction. That this barbarism should have survived into an age when all other pioneer operations have been refined and perfected by constant thought and care, and that it should still be universally taught and widely practised, is an indication of the scant attention paid to the inguinal canal by men engrossed in more dramatic regions, and a blot upon modern surgery.

There is no particular technique involved in the operation for hernia beyond that which is common to good surgery in any part of the body,

the creed of gentleness which is associated with the names of Halsted, Lane and Moynihan. Each plane must be divided along anatomical lines, the tissues must be treated with the greatest gentleness, hæmostasis must be complete, obliteration of dead spaces absolute and asepsis faultless. The inguinal region, where the abdominal wall surmounts the extraordinarily difficult task of transmitting the nerve and blood supply not only of the testes but of the lower limb, while permitting free movement and powerful stresses in the muscles and great variation in the diameter of the blood-vessels, depends for its security upon a most delicate adjustment of muscular and fibrous planes. The operative handling of this region should be correspondingly delicate, and inguinal technique is more akin to that of the plastic surgeon than of the worker in the more simple department of the upper abdomen. I know more than a hundred surgeons whom I would cheerfully allow to remove my gall-bladder, but only one whom I should like to expose my inguinal canal.

The essential question that must be answered, in deciding upon the type of operation to be undertaken in any particular hernia, is "Can the normal mechanism of the canal be kept in this case, or must it be replaced by something different?" The normal mechanism embraces fibrous and muscular elements; the former can, to some extent, be repaired if damaged; the latter cannot. Operations for the radical cure of inguinal hernia may therefore be placed into three groups, according to the object they seek to attain:

I. *The standard operation for congenital oblique inguinal hernia* where the muscle defences are good and the fibrous framework unstretched. Here removal of the entire sac without damage to muscular or fibrous tissues, and accurate reconstruction, will ensure success.

II. *Operations for larger inguinal herniæ of the oblique type*, whether congenital or acquired, where the muscles are still good, but the margins of the internal ring have become stretched. In these, after removal of the sac, some plastic procedure upon the posterior wall, designed to strengthen it where weak and to restore the diameter of the internal ring to that of the cord, will probably be satisfactory. The inguinal muscles themselves must not be used for this repair, or damaged in any way.

III. *Operations for direct or large oblique herniæ* where the fibrous tissues are stretched and the muscles atrophied. Here there is no likelihood of the weakened muscles regaining their sphincteric

action, and a new mechanism, foreign to the body, but perfectly satisfactory if well planned and carefully executed, must be devised. Such operations usually involve the construction of new internal and external rings, rigid and placed far apart, and of a strong fibrous anterior and posterior wall to the canal. The muscles are necessarily used in such an operation, but they cannot, without further reinforcement, provide a sufficiently strong sheet to prevent recurrence.

I. The Standard Operation

(1) *The skin incision.* For the reasons given in the section devoted to the anatomy of the inguinal region, an incision in the suprapubic skin crease is advised for all operations for the radical cure of inguinal

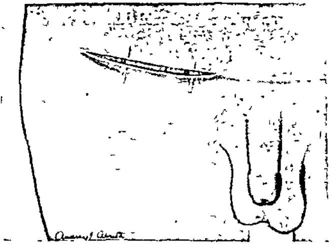

Fig. 1989.—Standard operation for inguinal hernia. The incision.

hernia. After identification of the crease, two light scratches are made across it with the back of the knife, to ensure accurate spacing of the flaps when they are subsequently sutured (fig. 1989). The cut should be made with a continuous sweep of the knife, while the skin is put on the stretch with the finger and thumb of the left hand, and should extend in the crease from a point ¾-inch outside Poupart's ligament nearly to the mid-line. In the wound, which is thus made to gape, the two branches of the superficial femoral vessels will be seen immediately, and should be divided between artery forceps, and ligatured with fine catgut. The surgeon then grasps the mid-point of the lower skin flap with toothed dissecting forceps and pulls it upwards, while his assistant does the same with the upper flap. A bold sweep with the knife through the superficial fascia, which is thus drawn strongly from the abdominal wall, will immediately lay bare the areolar plane between fat

and external oblique aponeurosis. The correct plane exposed, the surgeon quickly reflects the fatty layers off the external oblique, *downwards as far as Poupart's ligament, and upwards and outwards to* one inch beyond the internal abdominal ring (fig. 1990). Dissection with the knife should not be carried down to the external ring, as many small vessels pierce the intercolumnar fascia and are difficult to secure if divided; when the aponeurosis is cleaned so far, a downward sweep with a gauze swab will display the pillars of the ring and the emerging cord. Poupart's ligament should be laid bare at this stage down to its insertion, in order to facilitate subsequent suture of the pillars.

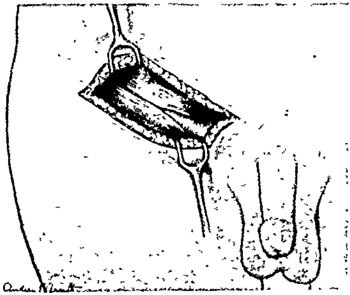

Fig. 1990.—STANDARD OPERATION. REFLECTION OF THE SUPERFICIAL FLAPS.

(2) *Reflection of the external oblique aponeurosis.* The external oblique should be incised towards the external ring and not from it, as this method carries a risk of injury to the cremaster or ilio-inguinal nerve. A cut about half an inch long is made with a knife in the aponeurosis in the line of the pillars, and about $\frac{3}{4}$-inch from the point where they diverge. The upper leaf is held up with dissecting forceps, and the cut extended with Mayo scissors into the external ring, and carefully beyond it into the intercolumnar fascia; the cut is then extended outwards in the line of the fibres to a point one inch above the internal ring.

The upper leaf is then reflected off the underlying structures, which are gently detached from its deep surface with sweeping strokes of the closed Mayo scissors, working from above down in the line of the arched fibres of the internal oblique (*fig. 1991*). Separation is continued till the outer border of the rectus sheath is exposed. The lower leaf is treated in a similar manner, till the inner surface of Poupart's

ligament is cleared as far as its insertion into the pubic bone; the fibres of the cremaster will be separated where they lie in contact with the aponeurosis, but their origin from Poupart's ligament must on no account be disturbed. When this stage is complete, the cord will be seen completely clothed in the fibres of the cremaster muscle on the surface of which lies the ilio-inguinal nerve.

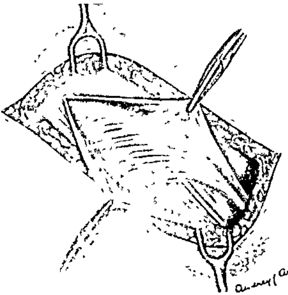

FIG. 1991.—STANDARD OPERATION. REFLECTION OF THE EXTERNAL OBLIQUE APONEUROSIS.

(3) *Reflection of the cremaster muscle.* The surgeon picks up the cremaster muscle with toothed dissecting forceps half an inch below the ilio-inguinal nerve and directs his assistant to do the same a quarter of an inch below it. A bold cut with Mayo scissors into the fold thus raised will open the sub-cremasteric areolar space. The closed points of the scissors are pushed up and down in this space to clear the cord, and the muscle is then divided in the line of its fibres, downwards to the centre of the external ring, and upwards to within a quarter of an inch of the arched fibres of the internal oblique. The surgeon now releases the lower leaf of the cremaster and, picking up the cord with his forceps, frees it by a few gentle touches of the closed Mayo scissors from the upper leaf of muscle, which is still held by his assistant (fig. 1992). The assistant then releases this leaf and takes the cord, while the surgeon picks up the lower muscular sheet and separates it in a similar manner. The cord is now free, and can be hooked up on the forefinger of the left hand, while the cremaster is pushed backwards from its two extremities with a gauze swab. The cord ly[illegible] the finger is covered with infundibuliform fascia only, and [illegible]stituents, normal or abnormal, can be clearly seen.

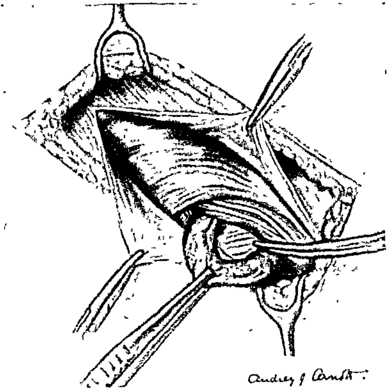

Fig. 1992.—Standard operation. Reflection of the cremaster muscle from the cord.

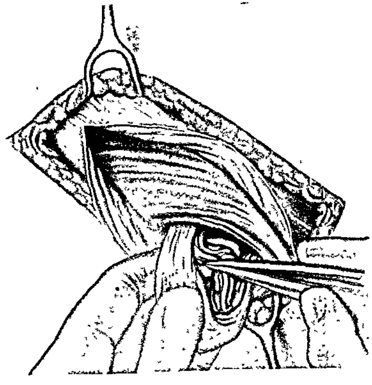

Fig 1993.—Standard operation. Isolation of the sac from the cord bundle.

ligament is cleared as far as its insertion into the pubic bone; the fibres of the cremaster will be separated where they lie in contact with the aponeurosis, but their origin from Poupart's ligament must on no account be disturbed. When this stage is complete, the cord will be seen completely clothed in the fibres of the cremaster muscle on the surface of which lies the ilio-inguinal nerve.

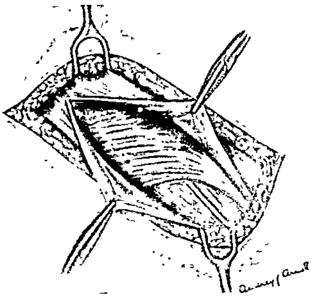

Fig. 1991.—STANDARD OPERATION. REFLECTION OF THE EXTERNAL OBLIQUE APONEUROSIS.

(3) *Reflection of the cremaster muscle.* The surgeon picks up the cremaster muscle with toothed dissecting forceps half an inch below the ilio-inguinal nerve and directs his assistant to do the same a quarter of an inch below it. A bold cut with Mayo scissors into the fold thus raised will open the sub-cremasteric areolar space. The closed points of the scissors are pushed up and down in this space to clear the cord, and the muscle is then divided in the line of its fibres, downwards to the centre of the external ring, and upwards to within a quarter of an inch of the arched fibres of the internal oblique. The surgeon now releases the lower leaf of the cremaster and, picking up the cord with his forceps, frees it by a few gentle touches of the closed Mayo scissors from the upper leaf of muscle, which is still held by his assistant (fig. 1992). The assistant then releases this leaf and takes the cord, while the surgeon picks up the lower muscular sheet and separates it in a similar manner. The cord is now free, and can be hooked up on the forefinger of the left hand, while the cremaster is pushed backwards from its two extremities with a gauze swab. The cord lying on the finger is covered with infundibuliform fascia only, and all its constituents, normal or abnormal, can be clearly seen.

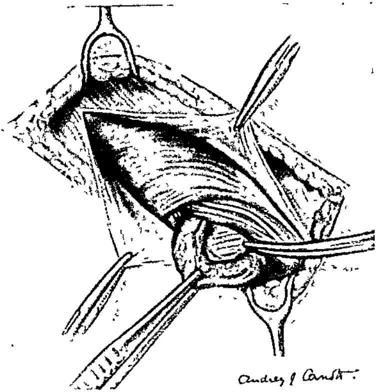

Fig 1992.—STANDARD OPERATION. REFLECTION OF THE CREMASTER MUSCLE FROM THE CORD.

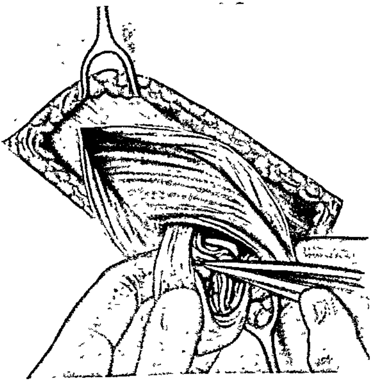

Fig. 1993—STANDARD OPERATION. ISOLATION OF THE SAC FROM THE CORD BUNDLE.

(4) *Isolation and ligature of the hernial sac.* The cord, still held up by the left hand, is incised longitudinally for about 1½ inches by a gentle stroke of the knife, which divides the infundibuliform fascia only. The sac, which has already been seen lying anteriorly in the bundle, now prolapses through this cut, completely denuded in its superficial aspect. It is picked up with a pair of Spencer Wells forceps which are then fixed by the thumb of the left hand, and thus held firmly on the pulp of the left index finger. With a pair of non-toothed dissecting forceps, all structures adhering to the sac are gently separated from it, working transversely to its long axis (fig. 1993). As succeeding parts of the sac are laid bare, they are gathered up with the left thumb, bringing a fresh portion into view for clearance. Finally, the point of commencement will be reached, and the index finger will be seen in a space which separates the sac from the cord. If the plane of dissection has been kept close to the wall of the sac, there is no danger of the vas deferens having been left attached to it, but the surgeon should always assure himself at this stage, by feeling the cord, that the vas is actually with the vessels and not with the sac. This dissection once begun must be pursued methodically in a plane transverse to the axis of the cord till two separate bundles emerge—the sac and the normal constituents; the left thumb must not relax its grip on the sac, and the temptation to wander up or down the cord must be resisted.

The vas and the vessels are kept in one bundle by enclosing them in the loop of a pair of Lane tissue forceps, and separation of the sac is continued towards the fundus in a similar manner, the sac being fixed by the left hand and the other structures peeled off it with blunt dissecting forceps. At the fundus some difficulty may be encountered. The tunica vaginalis is often continued upwards to a point which extends to the external ring and is adherent over a wide area to the expanded and flattened termination of the sac. The veins, increasing in size as the testicle is reached, are also firmly adherent to it, and the vas may lie in a loop on its walls, deviating from its previously straight course. Many of the bands are so tough that they must be cut by the knife. By working gently and methodically, holding the cord on the stretch and pushing its constituents from the sac with gauze and closed scissors, and using the knife only for strands that stand out clearly between structures already isolated, the separation will be effected without damage or bleeding.

When the fundus is free, the assistant draws the cord downwards and inwards, putting it on the stretch, and the surgeon, drawing the sac outwards, proceeds to clear its neck. The vas and veins are clearly

seen and easily separated by strokes with the closed scissors. The fibrous sheath should here be treated with great respect, not torn apart, but snipped with scissors close to the sac. As the neck is reached, a small retractor must be inserted under the upper leaf of the cremaster, drawing this muscle and the lower fibres of the internal oblique upwards and outwards. In an undilated sac the site of the neck can be recognised *without difficulty; its diameter expands suddenly*, the peritoneum becomes thinner, a tongue of extra-peritoneal fat appears beside it, and the deep epigastric vessels are seen below it. Except in those very thin sacs whose emptiness can be seen without any doubt, the fundus should now be cut and held open with three forceps, the interior of the

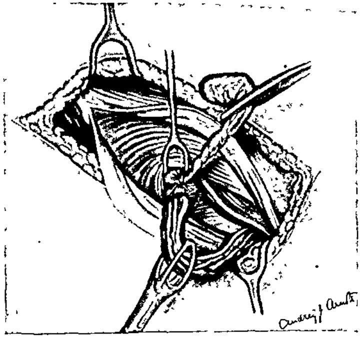

Fig 1994.—Standard operation. Twisting and ligature of the neck of the sac.

tube inspected, any contents returned, and a blunt instrument passed through the neck into the peritoneal cavity to prove that *no contents* are adherent at the neck. The cut fundus is then grasped in the jaws of *one pair of artery forceps, and twisted repeatedly, till the turns* reach the internal ring (fig. 1994). This torsion of the sac serves two purposes: it obliterates the whole cavity and ensures that no loop of gut or tag of omentum can enter at the last minute and be pierced during transfixion of the sac, and it provides a narrow pedicle for ligature. The sac is held up while its twisted neck is pierced with a round needle carrying No. 1 catgut and tied, first on one side, then on the other, and finally all round in the groove made by the first two knots. The ligature is cut and the sac divided half an inch beyond it; the stump recedes immediately behind the aperture in the transversalis fascia and disappears from view.

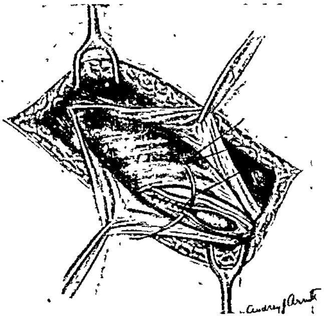

Fig. 1995.—STANDARD OPERATION. REPAIR OF THE CREMASTER MUSCLE.

(5) *Repair of the inguinal canal, and closure of the wound.* When the neck of the sac has been cut and the surgeon has satisfied himself, by gentle palpation, that the internal ring is unstretched, the layers are closed in sequence.

The cord is pushed down into the scrotum till it lies level with the floor of the canal, and the cut edges of the cremaster muscle are picked up near the internal ring. A continuous suture of No. 00 catgut on a fine round-bodied needle will serve to unite this layer over the cord (fig. 1995). The fibres have not been cut across and the sutures require no more tension than is necessary to approximate the edges of the cut. Care must be taken that the ilio-inguinal nerve is not caught up.

The external oblique aponeurosis is sutured with No. 1 catgut on a round-bodied needle, starting at the lateral end of the wound. As the inner end is approached it is important to make sure that each stitch takes a bite of the firm fibres constituting the pillars, and not merely of the thin expanded aponeurosis that lies between them (fig. 1996). The suture should be continued inwards till the external ring is reduced to a size that will just transmit the cord comfortably—that is, to the diameter of the last joint of the little finger; the last stitch should therefore be held tight, and the diameter of the ring tested before it is finally tied.

Accurate closure of the cutaneous layers is an important step in the crease operation for hernia. Three or four sutures of No. 00 catgut on fine, curved needles are passed in the following way: The needle is passed from the deep surface of the upper flap, traversing the fascia

of Scarpa and then that of Camper, to emerge close under the skin. It is re entered close under the skin on the lower flap at the corresponding point (which is identified by the skin scratches made before the operation was started) and passed down through the two fatty layers to emerge on the deep surface of Scarpa's fascia (fig 1996) These sutures, when tied, obliterate all dead space between the operation site and the flaps which cover it, evert and at the same time relieve the skin margins of tension, and carry their knots at the greatest distance from the skin, where they are almost immune from the "catgut ooze" that will often spoil a promising incision The skin is closed with Michel clips, the scratches being first brought together, after which the intervening spaces are approximated (fig 1997)

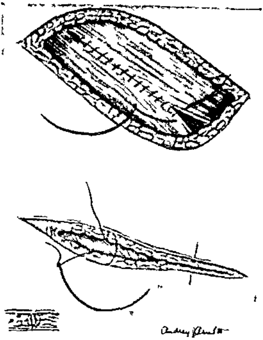

Fig 1996—STANDARD OPERATION
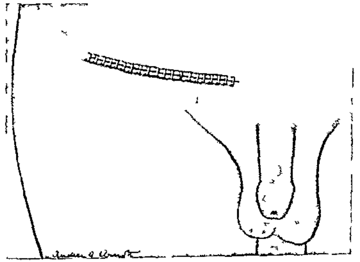
(*Top*) REPAIR OF EXTERNAL OBLIQUE APONEUROSIS
(*Bottom*) SUTURE OF THE SUBCUTANEOUS LAYERS

(6) *After-Treatment* The care of a hernia case differs little from that of any other operation of moderate severity, and any detailed instruction would be out of place Two points, however I consider important

First, that in the crease incision all clips should be removed in forty eight hours Where the incision has been placed in a plane of no

Fig 1997—STANDARD OPERATION CLOSURE OF THE INCISION



movement, and where the deeper layers have been brought together and the skin accurately apposed, clips or sutures are no more than approximating devices. Their retention after forty-eight hours serves *no purpose, and invites sepsis.*

Secondly, that the patient should remain in bed for three weeks. A good inguinal canal after a hernia operation demands fibrous planes reconstructed by repair tissue which has been subjected to no premature strain. The patient may, after forty-eight hours, assume any position in bed that he likes if his general condition warrants it, but recumbency should be insisted upon.

Alternative incision. That commonly employed is a straight incision, parallel to Poupart's ligament and about half an inch above it, extending from a point ¾-inch outside the internal ring to one overlying the centre of the external ring. This is shorter than the crease incision and gives more direct access, and will be preferred by the surgeon who is inexperienced, badly assisted, or otherwise working under difficulties.

Alternative methods in isolating the sac. Many text-books describe, and many surgeons practise, a search for the hernial sac as soon as the external oblique aponeurosis has been reflected. It is quite possible to isolate a hernia in this way, but not easy, for the cremasteric fibres hide the structures which they still envelop, nor wise, for a muscle which has been avulsed as an obstruction to vision will never regain its normal function.

SPECIAL POINTS IN THE ISOLATION AND LIGATURE OF THE HERNIAL SAC

(1) *The separation of a very thin-walled sac.* In some inguinal herniæ, particularly the complete congenital herniæ of children which extend into the tunica vaginalis, and those associated with an undescended testis, the walls of the sac are extremely thin and fragile, and adherent to the structures of the cord to an unusual degree. In spite of the greatest gentleness, the peritoneum is torn in an attempt to strip the vessels from it. The margins should then be seized with hæmostats, and the attempt continued. If further tears appear, the surgeon may allow the sac to gape, and, guided by vision, gently work the point of a blunt dissector or one blade of a pair of dissecting forceps between the peritoneum and the cord. When the correct plane has been established at one level, the sac can then be stripped up and down with a little care.

In some herniæ even this manœuvre will fail. It has been my

practice in such cases to open the sac with scissors on its anterior aspect to within half an inch of its neck, and to get my assistant to hold the margins apart in mosquito forceps while he makes traction on the cord. The neck of the sac, now seen from within as a small funnel, can be cut round with the point of a fine knife or with Mayo scissors, the cut extending through peritoneum only, and each segment be picked up with a further pair of mosquito forceps as it is divided. When the peritoneum has been divided all round the neck, the forceps are held up together, the neck cleared from the cord by a few strokes of the closed scissors, and tied off. It is unnecessary after this to remove more of the body of the sac than its anterior wall, which should be cut away freely, leaving the posterior wall still clothing the cord.

(2) *The treatment of the tunica vaginalis in congenital hernia.* Where the hernial sac is continuous with the tunica vaginalis, there is no "fundus" in the sense of a rounded termination that can be removed in continuity with the body. The surgeon may either carry the separation of the sac to the upper pole of the testis, and there divide it, closing the distal half with a simple ligature or a purse-string suture, to leave a tunica vaginalis; or he may carry his dissection into the scrotum and remove the parietal layers of the tunica vaginalis with the sac—combining a "radical cure" of hydrocele with that for the hernia. The choice will depend ultimately upon the operator's personal views upon the inevitable wisdom of all Nature's handiwork. The tunica vaginalis is a normal structure and must serve some purpose; on the other hand, a hydrocele is perhaps slightly more common after a hernia operation than it is in the average population, and removal of the outer serous layers does not seem to carry any recognisable disability. I personally reconstruct the tunica vaginalis in the child, and obliterate it in the adult.

(3) *The removal of lipomata.* Any lipomata lying in the inguinal canal should be removed as part of the operation of radical cure. They stretch the muscles, interfere with efficient action of the sphincteric mechanism and, when springing directly from the extra-peritoneal fat, undoubtedly lead to recurrence by dragging down a fresh pouch of peritoneum. Such lipomata are preferably removed as soon as the reflection of the cremasteric layer is complete, and before the sac is disturbed; they can then be seen clearly and removed completely, whereas later they are stained with blood and are less distinct. The pedunculated lipoma which passes through the internal ring beside the sac should be crushed and ligatured before it is divided.

(4) *Other means of treating the neck of the sac.* Various surgeons

have used the sac itself as a material for reinforcing the region of the internal ring. Macewen passed a catgut suture through the fundus of the sac, and then from side to side through its body, so that when pulled tight it drew the sac into concertina folds; the free ends of this suture were threaded on a hernia needle and passed upwards through the internal ring lateral to the sac, being finally pushed through all muscular layers about an inch lateral to this point and tied on the surface of the external oblique aponeurosis. Kocher grasped the fundus of the sac with a pair of curved forceps and invaginated it, forcing the end of the forceps through the parietes lateral to the internal ring; here the redundant part of the sac was cut off, and the stump stitched to the parietes. These operations are of little more than historical interest to-day. Such dislocation of the sac does not ensure the smooth unbroken peritoneal surface on the abdominal aspect of the inguinal region which is attained by ligature of the sac at the correct level, while it damages the fascial planes of the internal ring and the muscles above this to no real purpose. Ligature of a sac which has been isolated to its commencement with the greatest gentleness, and divided half an inch beyond the ligature, will leave a smooth peritoneum, backed up by an undamaged fascial layer, and reinforced behind the peritoneal scar by a fibrous plug.

INGUINAL HERNIA IN THE FEMALE

The female inguinal canal follows the same general arrangement as the male, with such modifications as are dependent upon its differing contents. The round ligament is smaller and less vascular than the cord, and is not subjected to the same movements and alterations in diameter. The channel is therefore smaller, the cremaster inconspicuous, and the conjoined muscle forms a less obvious arch, running close above and almost parallel to Poupart's ligament. Inguinal hernia in the female is nearly always due to the persistence of a congenital sac, and this sac is usually blended with the round ligament and extends well into the labium majus. To separate the sac from the round ligament without damage to either structure is a difficult and tedious matter, and in the opinion of the majority of surgeons unnecessary. The round ligament curtailed at the internal ring can apparently carry out its suspensory functions with regard to the uterus, whatever they may be, as efficiently as when it is continued into the labium.

The steps of the operation are identical with those of the standard repair in the male, down to the stage when the cremaster is reflected

from the round ligament. The sac and round ligament are now held up together on the index finger of the left hand, and pulled gently while their distal extensions are cleared from the tissues in the labium by blunt dissection. When the fundus of the sac has been brought into view, any remaining strands of tissue, including the termination of the round ligament, may be clamped, tied, and cut across. The round ligament and sac are now held up and cleared as far as the internal ring. The sac is usually so thin that it can be seen whether it is empty ; should there be any doubt, it should be opened for inspection and for the passage of a probe. This point settled, the sac-round-ligament bundle is crushed at the neck with Ochsner forceps, transfixed, tied with catgut, and cut across half an inch beyond the ligature. Since the canal is now empty, it should be obliterated by three sutures of No. 1 catgut, passed through the conjoined and cremaster muscles and Poupart's ligament, and tied sufficiently tightly to approximate but not to cut into the muscles.

II. The Standard Operation, as Modified for Larger Herniæ of the Oblique Type

The standard operation just described is that which offers the best chance of permanent cure in an oblique hernia where the muscular defences are intact, the fibrous posterior wall of the canal sound, and the internal ring unstretched. Many cases are met with, however, in which the internal ring has become damaged while the remainder of the mechanism of the canal remains comparatively sound. The neck of a congenital oblique hernia lies above and to the outer side of the cord, and in its early days represents a potential space only, which does not dilate the fibrous collar of the internal ring. With the repeated entry of abdominal contents into the sac, and particularly with their lodgment there, the ring becomes stretched to accommodate cord plus sac. To start with, the stretching is in that part of the circumference occupied by the sac, that is, the upper and outer segment, and the *inner border of the ring is not displaced.* With time, however, the whole ring becomes dilated, the inner border, and with it the deep epigastric artery, is displaced medially, and the cord, though still bearing the same relation to the neck of the sac and the artery, leaves the posterior wall much nearer the mid-line than is normally the case.

These observations have an important bearing upon the steps necessary for the repair of the internal ring. Estimation of the size, degree of shift, and strength of the borders of the ring is more easily made by touch than by sight. The size of an unstretched ring is the

diameter of the cord when engorged with blood, roughly that of the last joint of the little finger. Such a ring requires no repair. If the surgeon finds that the site where the sac has been tied and cut off appears as a weak area lying outside the cord, but that the cord is not displaced medially, that the inner margin of the ring is firm, and that the deep epigastric artery runs a straight course, he will be content with some simple approximation of the edges of the defect in the transversalis fascia over the stump of the sac. If, on the other hand, he finds that the ring as a whole is dilated, the cord displaced and the artery shifted, he can only restore normal relations by moving the cord outwards to

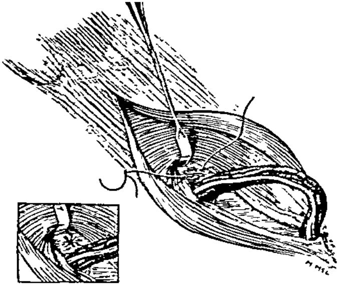


Fig. 1998.—Reconstitution of defect in internal ring: first method.

that part of the ring formerly occupied by the neck of the sac, and repairing the weak area to its medial side.

(1) *Simple suture of the defect in the internal ring.* The weak area must be exposed by drawing the cremaster and internal oblique muscles strongly upwards with a small retractor, thus bringing into view the transversalis fascia lateral to the cord, the stump of the divided sac, and the defect around it. The margins of the defect are defined by palpation and brought together by a stitch of No. 1 chromicised catgut, the needle taking a bite of firm fibrous structures. Two methods of closure may be recommended in these borderline cases:

(*a*) The Arbuthnot Lane "X" stitch (fig. 1998), which draws the edges of the defect over the peritoneal stump.

(*b*) A mattress stitch passed on a round-bodied needle, first through Poupart's ligament about half an inch lateral to the internal ring, under the conjoined muscle, to emerge at the ring, then

out through the upper margin of the defect and back through its inner margin, and then back under the muscles to pierce Poupart's ligament again about ¼-inch from its point of entry. This stitch, which is easily understood by reference to the diagram (fig. 1999), draws the margins of the defect together, and the whole weak area outwards.

(2) *Reconstruction of the internal ring.* After ligature of the sac, the cord must be displaced to the outer and upper part of the stretched ring, and held there by a retractor, which at the same time keeps back the muscles and exposes the inner part of the defect. The margins of

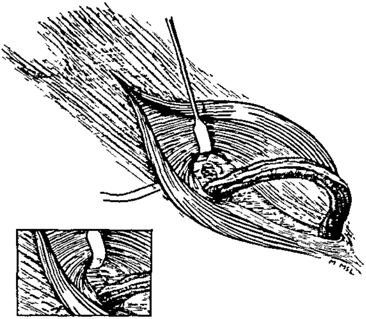

Fig. 1999.—Reconstitution of defect in internal ring: second method.

what should be the ring can be felt more easily than seen, but after identification they may be defined by careful snipping away of loose tags of fascia and muscle. It is essential that the repair material should be anchored at its edges to firm fascial tissue.

(*a*) *Silk reinforcement.* I personally prefer the use of silk to any other method, as it does not involve dislocation of, or injury to, any of the normal structures of the canal or its neighbourhood, it is rapid, easy, and atraumatic, and it forms the basis of a tough and permanent fibrous sheath. A length of No. 4 Chinese twist silk on a small, curved needle (the particular needles I use are small Symonds needles with the shank shortened to make them into a half-circle instead of fish-hook shape; these are sold by the Medical Supply Association Ltd., 95 Wimpole Street, W.1, as " Ogilvie No. 5 ") is passed through the inner margin of the

stretched ring previously defined, and through Poupart's ligament just below this, and knotted (fig. 2000). The short end is caught in a hæmostat. The silk is worked backwards and forwards across the weak area, taking alternate bites of ring margin and Poupart's ligament, and drawn tight enough to lie straight, but not to exert any tension. This darning is continued outwards till the ring is reduced to an opening which exactly fits the cord, lying well out and under cover of the internal oblique. The silk is then knotted on itself and continued back, taking bites of Poupart's ligament between the

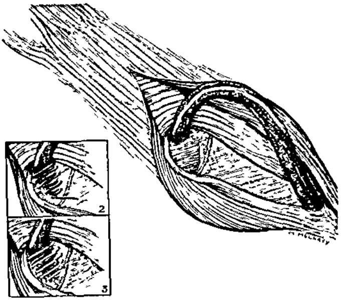

Fig. 2000.—Repair of internal ring by silk lattice.

1. The internal ring defined
2. First layer of silk.
3. Second layer of silk.

former stitches and of the transversalis fascia a few millimetres outside the ring margin. When the starting-knot is reached, the two ends of silk are tied together and cut short.

(*b*) *Fascial strip darning.* A repair, similar in all essentials to that described with silk, may be performed with one or two fascial strips. The strip may be taken from the fascia lata of the thigh with a fasciatome. Alternatively, a ribbon cut from the external oblique aponeurosis, and left attached at one or other end, may be used for the same purpose. I have used a strip cut from the upper leaf, left attached at its outer end, and brought to the internal ring through a tunnel in the muscles, arguing that such a strip would automatically become tense when the abdominal muscles contracted (fig. 2001). The belief that any isolated strip of muscle continues to act as

such is probably erroneous, but, at any rate, the repairs carried out by this method have stood the test of time.

(c) *Turner's operation.* Mr. Philip Turner repairs a badly stretched internal ring by turning up a flap of fascia lata from the thigh under Poupart's ligament and suturing it to the margins of the defect medial to the cord. Philip Turner (*Guy's Hospital Reports*, 1933, XIII, 2, 233) writes: "The essential feature of the operation is that a pedicled flap of fascia lata with its base at Poupart's ligament is used for the purpose of diminishing the size of the opening and strengthening the fascial boundary of the canal. The flap is turned upwards

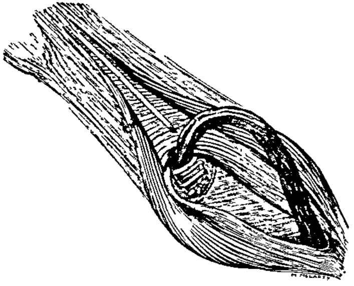

Fig 2001 —Repair of internal ring by pedicled strip of aponeurosis

beneath Poupart's ligament into the inguinal canal, and is sutured to the margins of the gap which have been carefully defined at an earlier stage. . . . The original deep surface of the flap, which was in contact with the muscles of the thigh, looks forward, while the original superficial surface, in relation with the fatty tissues of the thigh, is now in contact with the extra-peritoneal fatty tissue at the back of the inguinal canal." Reference to figure 2002 will explain the essential features of this operation.

In all of the above operations, the cremaster is carefully sutured over the cord, as in the standard operation.

III. Reconstruction of the Inguinal Canal

The operations hitherto described have been based upon the preservation or restoration of the normal inguinal mechanism. When,

however, this mechanism is beyond repair, something much more elaborate and drastic is required—the replacement of Nature's handiwork by that of man. The decision that such reconstruction is necessary is therefore one of considerable importance.

The defences of the inguinal canal are based upon a system common to the whole locomotor apparatus of the body—a fibrous framework protected by a muscular guard, much as the defences of a frontier consist of mechanical fortifications manned by living troops. Under repeated attacks the forts may be destroyed but the garrison remain effective, or forts and garrison may be overwhelmed together; but it is

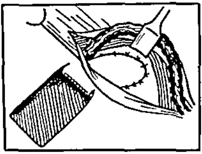

Fig. 2002.—Turner's operation.

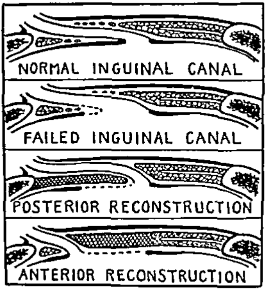

Fig. 2003.—Diagram to illustrate alternative methods of reconstructing the inguinal canal.

unlikely that the soldiers would be put out of action while the fortifications remain undamaged. So in the inguinal canal the fibrous planes alone may suffer, the muscles may atrophy with or after the fibrous planes, but the muscles cannot give way alone, leaving the fibrous tissues intact.

Reconstruction is necessary when the fibrous planes have yielded to such an extent that repair is impossible without encroaching on the muscles, or when, with a lesser degree of fibrous tissue damage, the muscles are also inefficient. Any yielding of the posterior wall itself, that is, of the part medial to the deep epigastric artery, is an absolute indication for reconstruction. Enlargement of the ring lateral to the deep epigastric artery is remediable if the stretching is moderate, the margins of the defect firm and defined, and the inguinal muscles good; but beyond a certain point, which for practical purposes may be taken

as a diameter of 3 cms., the enlarging ring encroaches to such an extent on the posterior wall that the failure becomes a general one of the fibrous planes of the canal. An estimation of the condition of the muscles is therefore of decisive importance only in those cases where the *fibrous defect is considered reparable provided the muscles can play* their part. Replacement of the fibres of the cremaster by connective tissue or fat, a general bulging of the conjoined muscle, or a pale flabby appearance of its fibres, will determine the surgeon to reconstruct rather than to restore.

The reconstruction of a failed inguinal canal would be simple were the surgeon given the relatively straightforward task of closing the whole defect, as he would an incisional hernia, and not the more complex one of providing sound repair while allowing free passage to the spermatic cord. Castration can only be considered in exceptional cases, while the expedient of reducing the diameter of the cord by excising the greater part of the pampiniform plexus, a step which formed part of the original Halsted operation, has been abandoned because of the unfortunate sequelæ—pain, hydrocele, and atrophy of the testis—which follow it in many cases. The problem has been approached in many ways, but the *suggested operations fall into two great sub-divisions: the operations* of repair anterior to the cord, and the posterior repair operations. The student himself must decide which type of repair is the more rational, and be guided in his decision by principles rather than by the "witch words" with which surgeons, hardly less than parsons and politicians, are prone to suggest the answer by the way they word the question. Advocates of anterior repair claim that the cord is not "dislocated" from its bed; the same men do not "dislocate" themselves or their patients from bed, and employ a word suggesting violent rupture from firm natural bonds, because they have already decided that they do not wish to reach the posterior wall of the canal. In my opinion the deciding factor is that surgical repair depends ultimately upon the production of firm fibrous tissue, and a fibrous channel transmitting a bundle of blood-vessels must be long and oblique to be secure. An efficiently performed posterior repair will transmit the cord through two openings, each rigid and of the required diameter, and placed far apart in strong anterior and posterior walls. Anterior repair, which takes no cognisance of the posterior wall, may make a rampart equally strong, but the channel which it leaves for the cord will eventually become a direct one, lying close to the pubic spine (fig. 2003).

I propose, therefore, to describe first the operation of posterior reconstruction, giving preference to those methods which I have

personally found satisfactory, and to follow those with a short description of other methods of posterior repair, and of representatives of the anterior method which are favoured by surgeons in many parts of the world.

(1) *Silk lattice repair of the inguinal canal.*

The reconstruction operation described is based upon the Gallie method of fascial suture, and the " darn and staylace " method, which was well described by Sampson Handley in the June 1918 issue of *The Practitioner.* The advantages and disadvantages of silk and fascia have been discussed on page 3610.

The preliminary steps are those of the standard operation described on page 3626. The skin-crease incision is advised, and, where silk is used, has the additional advantage that the early removal of sutures, and the divergence between the plane of the incision in the sub-

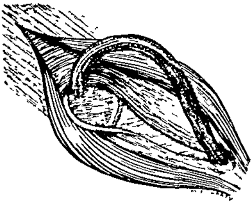

Fig. 2004.—POSTERIOR RECONSTRUCTION OF THE INGUINAL CANAL WITH SILK. FIGURE SHOWS THE INTERNAL RING STRETCHED AND THE EPIGASTRIC ARTERY DISPLACED MEDIALLY.

cutaneous layers and that of the musculo-aponeurotic structures, provide further safeguards against chance infection from without. The external oblique and cremasteric layers are divided and reflected in turn, and the cord lifted from its bed (fig. 2004). If the hernia is an oblique one, the sac is separated from the cord in the usual way, isolated to its neck, ligatured and cut off; if it is direct, the sac should, except for very special reasons, be left undisturbed. To excise the wide sac of a direct hernia adds nothing to safety, for such herniæ do not strangulate; it does not increase security, for it stretches thinned tissues still further: on the other hand, it may involve the risk of wounding the bladder, and in any case produces a scar on the peritoneal surface of the inguinal region.

The aim of the operation being to produce a uniform fibrous sheet protecting the whole posterior wall of the inguinal canal, and leaving only an aperture for the passage of the cord, it is first necessary to prepare the two ends of the canal (fig. 2005). At the medial end the

repair must extend down to the meeting-point of the insertions of Poupart's ligament and the rectus sheath on the body of the pubis. This point is covered and obscured by the fibres of the cremaster which sweep from the inguinal canal into the scrotum. It is therefore necessary to cut round the cord at this level with scissors, so that the muscle-fibres drop back into the inguinal canal and the cord itself remains bare: *a small artery in the cremaster usually requires ligature at this point.* At the lateral end of the canal it is necessary to reconstruct an internal ring lying at the periphery of the weakened one. The muscles are therefore retracted and the cord pushed to the outermost part of the stretched ring. If, in the case of a large oblique hernia, the ring has been so dilated that its outermost part cannot be reached by retraction, the internal oblique may be divided at its origin from Poupart's ligament for a distance of half an inch to provide access.

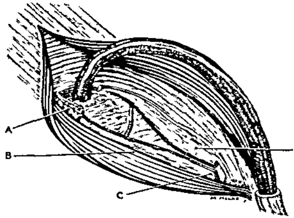

Fig 2005.—POSTERIOR RECONSTRUCTION. PREPARATION OF THE TWO ENDS OF THE FAILED INGUINAL CANAL TO ALLOW THE POSTERIOR WALL TO BE REINFORCED THROUGHOUT ITS LENGTH

A. INCISION OF INTERNAL OBLIQUE TO ALLOW THE END TO BE DISPLACED TO THE OUTERMOST LIMITS OF THE STRETCHED RING. THIS STEP IS NECESSARY ONLY IN THE WORST CASES.
B POUPART'S LIGAMENT
C AND D LOWER AND UPPER FLAPS OF CREMASTER CUT FREE FROM CORD TO ALLOW ACCURATE CLOSURE OF THE DEFECT AT ITS INNER END.

The lattice is constructed with a strand of No. 4 Chinese twist silk, boiled, soaked in $\frac{1}{1000}$ flavine solution, and threaded on a small curved round-bodied needle (see pages 3639 and 3640). Twenty-four to twenty-six inches are required for a complete reconstruction, but as such a length is unwieldy I usually work with an 18-inch suture and join another for the return layer. The first stitch takes a firm bite of the deep aspect of Poupart's ligament at its insertion into the pubic spine and of the conjoined tendon where it becomes anterior rectus sheath in the immediate vicinity (fig. 2006; see also fig. 2015); the silk is knotted and the short end caught with artery forceps. The cord is then held out of the way while the suture is continued in a lateral direction, taking first a bite of the recurved edge of Poupart's ligament, then of each side of the cremaster, then of conjoined tendon, and then back to Poupart's ligament. The stitches are placed about four to the inch, and are drawn tight enough to lie straight, but not to put any strain on Poupart's ligament or to pull it out of line. As the internal ring

is approached, the cord is held firmly outwards with the muscles, and the suture is continued till it can be felt that only an opening the size of the tip of the little finger remains below the arch of the muscles.

The next step is to reinforce the ring. The silk is knotted on the

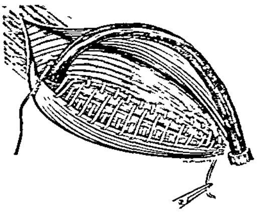

Fig. 2006.—Posterior reconstruction. Insertion of the first row of silk sutures.

conjoined tendon; then carried transversely across above the cord, passed through muscle and knotted again; then brought downwards to pick up Poupart's ligament lateral to the cord and once more

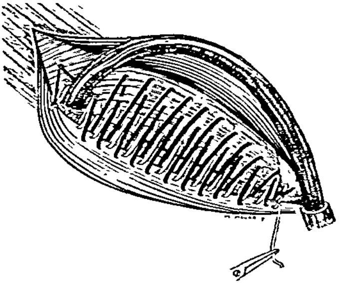

Fig. 2007.—Posterior reconstruction. Insertion of the second row of silk sutures.

knotted; the three stitches are then repeated in the reverse direction, being knotted at each angle so that the emerging cord is surrounded by a double ring of reinforcing silk.

The suture is now continued back to the inner side of the canal with a wider traverse, taking on the one side a bite of the free edge of Poupart's ligament between the stitches of the previous row, and on the

other the aponeurotic structures where the oblique muscles become tendinous at the outer border of the rectus (fig. 2007). As before, each stitch is pulled firm but not tight. When completed, the latticed area should present a definite resistance to the finger like last year's tennis racket, but the stitch holes should nowhere show any evidence of tension. At the inner end of the canal the free silk is tied to the first suture and both are cut short.

The cord is now laid back on its new bed, the external oblique aponeurosis repaired, with overlap if it has been much stretched, and the superficial layers closed in the manner previously described.

(2) *Gallie's operation.*

Gallie's investigations into the repair of fibrous tissues, and his description of the operation of fascial suture as applied to the cure of large herniæ, have probably had more far-reaching effects and been of greater benefit to mankind than any surgical discovery of this century. By the methods he so ingeniously devised, many men who would otherwise have been condemned to a life of restricted activity have been returned to full work and health. For personal reasons that I have attempted to explain on page 3611, I prefer silk to fascial suture in the inguinal canal; but the method of Gallie, here described, is used with satisfaction by surgeons in every country.

The preliminary steps of the operation will be identical with those described for silk repair; the subsequent ones may be quoted from the author's article. (W. E. Gallie and A. B. Le Mesurier, *Brit. Journ. Surg.*, 1924, XII, 46, 315–319.) "The first suture of fascia lata, a quarter of an inch wide, is anchored securely into the rectus sheath close to its attachment to the pubic bone. The needle is now passed behind the spermatic cord to pierce Poupart's ligament at its insertion into the pubic spine. If possible it should be made to pick up the periosteum to make the security of its fixation more certain (fig. 2008). When the suture is drawn taut, the weakest spot in the abdominal wall, namely, that which lies behind the external abdominal ring, is filled with a tough aponeurotic tissue which effectively prevents any bulging through the ring. The sewing is continued in an outward direction, drawing the internal oblique muscle to the reflected portion of Poupart's ligament behind the cord, until the position of the internal ring is reached. Here the suture is locked and then carried to the outer side of the ring, where a supporting stitch is inserted. In this way the cord, at the point where it disappears through the abdominal wall, is surrounded by a fibrous ring which will effectively prevent the development of a hernia at this point. By locking each stitch at this stage the

possibility of undue constriction of the cord is prevented. The sewing of the internal oblique muscle to Poupart's ligament in this manner is a detail of the operation which in our opinion is of very little value in preventing recurrence of the hernia. It is of value, however, in permanently covering the peritoneum with a thick layer of muscle which will prevent the protrusion of peritoneum through the chinks of the next layer of sutures, which is the important one in the prevention of recurrence. This layer commences as a continuation of the first,

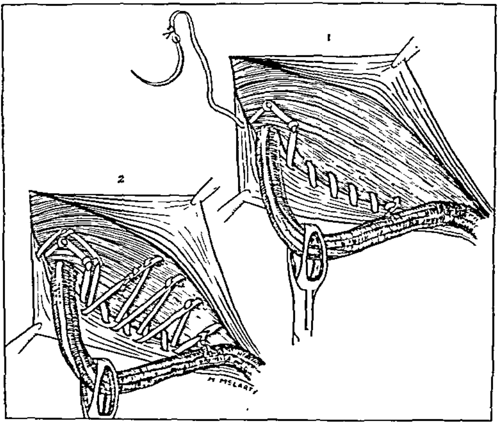

Fig. 2908.—Posterior repair of inguinal canal by Gallie's method.

at the outer side of the internal ring. The needle takes a solid bite of the abdominal aponeurosis at its point of fusion with the external oblique and is then passed behind the cord to pick up Poupart's ligament. *The suture is carried backward and forward across the space, with frequent lock-stitches, until the sheath of the rectus is reached,* and this also is woven to Poupart's ligament until the whole space is filled with fascia down to the pubic spine. No attempt is made with the second row of sutures to drag the abdominal aponeurosis and the rectus sheath out of their normal positions. No greater tension is exerted on the sutures than is sufficient to make them lie flat. The

whole idea of the operation is to fill the weak spot in the abdominal wall with what may be called a filigree of living aponeurosis, and to depend on the strength of this filigree and on its grip on the surrounding tissues for the cure of the hernia. What one does with the external oblique is of relatively little importance. Usually in direct hernia it is too weak to be of any value to the surgeon. In our earlier operations we closed it down to the external ring with a narrow strip of fascia, but in the last four years we have simply sewn it up with catgut."

(3) *Fascial repair by strips cut from the external oblique.*

Gallie's method of fascial suture may be carried out in suitable cases with strips ¼-inch wide cut from the upper and lower flaps of the external oblique aponeurosis. The strips are left attached at the pubic end, where they form part of the pillars of the external ring; their lateral end is divided where the aponeurosis joins the muscle-fibres, and is threaded through a fascial needle in the same manner as a strip cut from the thigh.

The advantages of such an expedient are apparent. The operation is shortened, no second incision is required, a local anæsthetic is quite adequate for the whole procedure, and the first anchoring stitch is avoided as the strips are already attached to bone. On the other hand, the fascial material is almost necessarily limited to two strips, and in a large hernia these may be of poor quality. The length of the strips will rarely exceed seven inches, and while it is quite possible with two such sutures to carry out Gallie's double reinforcement of the posterior wall, it is difficult to reinforce the internal ring with a two-fold girdle of fascia in the manner he recommends. The method is therefore eminently suitable for defects of moderate size requiring reconstruction, but inadequate for the major problems of inguinal repair.

The details of this operation, which resembles Gallie's in all essentials, can be understood by reference to the preceding section.

(4) *The Wyllys Andrews imbrication operation.*

This operation, published as long ago as 1895, has maintained its place as a soundly planned method of reconstruction of the posterior wall of the inguinal canal, which is eminently suitable for those cases where the tissues are sufficiently good to permit the firm imbrication of aponeurotic tissues, upon which its success depends. (Andrews, *Surg. Clinics of N. America*, 1934, XIV, 919.)

The skin incision and the exposure of the external oblique aponeurosis are made in the usual manner, except that the pillars of the external ring must be defined with particular care, and the subcutaneous tissues must be cleared from the aponeurotic layers a full inch below

Poupart's ligament. The incision in the external oblique is also made as in the standard operation, but must be so placed that the lower aponeurotic flap is sufficiently wide to cover the cord at the end of the operation—that is, it must lie at least 3 to 4 cms. above Poupart's ligament. When the aponeurotic flaps have been reflected the cremaster is incised, the cord lifted from its bed, and the hernial sac dissected out and ligatured in the usual manner. The essential part of this operation is that the inguinal canal is reconstructed by forming a strong fibro-muscular posterior wall behind the cord, consisting of conjoined tendon, cremaster and upper leaf of the external oblique aponeurosis. This flap is brought down to Poupart's ligament, in the original Wyllys

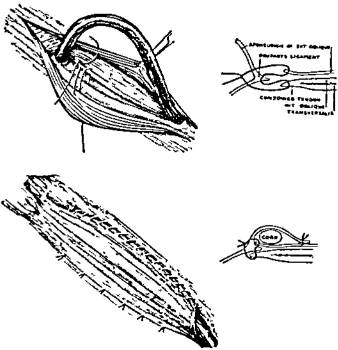

Fig. 2009.—Wyllys Andrews' operation.

(*Top*) Details of the "W" stitch which draws the conjoined tendon and upper leaf of the external oblique aponeurosis down to Poupart's ligament behind the cord

(*Bottom*) Suture of the lower leaf of the external oblique aponeurosis in front of the cord.

Andrews technique, by a small number of very stout mattress sutures of stout kangaroo tendon placed about 2 cms. apart (fig. 2009, top). There does not appear to be any particular virtue in the coarseness of the material or in the wide spacing of the stitches, and I have used sutures of No. 1 chromicised catgut with perfectly satisfactory results. The manner of inserting the stitches is, however, important. Each is passed, first from the deep fascia of the thigh below Poupart's ligament into the inguinal canal, while a finger guards the femoral vein from injury; then through the conjoined tendon and cremaster from within outwards, taking a generous bite of their substance; then back through the recurved edge of Poupart's ligament; then through the upper leaf

of the external oblique aponeurosis some distance from its edge; lastly, back through the lower leaf of external oblique very close to Poupart's ligament, to appear on the thigh close to its point of first insertion. This "W" stitch, which appears complicated in verbal description, will readily be understood by reference to figure 2009. The effect when the stitch is tied on the outer surface of the aponeurosis is to bring the upper aponeurotic flap and the conjoined muscular sheet down above and below the edge of Poupart's ligament, which projects between them (fig. 2009, inset). The first stitch should be right at the medial end of the canal, and should pass through Gimbernat's ligament; the last should be just medial to the point of emergence of the cord from the internal ring. Each stitch, as it is inserted, should be caught in artery forceps, and none should be tied till all are in place; if this precaution is neglected it may be difficult to secure the conjoined tendon with the later ones.

When all the stitches are tied, a firm posterior wall will have been constructed behind the cord. The cord is laid back on this bed just above Poupart's ligament, and the lower leaf of the external oblique aponeurosis is then sutured over it to make a roof for the canal (fig. 2009, bottom). Suture is started at the lateral end of the canal, and continued inwards till the external ring is reduced to the size of the tip of the little finger.

The essential requisite for Wyllys Andrews' operation is a good external oblique aponeurosis. In many cases where it would be most applicable, this layer is so stretched and thinned by an old-standing hernia and the pressure of a truss, that it is of little value as repair material.

Girard described a similar operation to that of Wyllys Andrews in 1898.

(5) *Other methods of posterior repair.*

(*a*) *Bassini's operation.* The skin is divided in the line of the inguinal canal, and the external oblique is exposed and incised from the external ring to a short distance above the internal one. The cord bundle is freed from cremasteric fibres, and the hernial sac isolated from the other structures in the cord as far as the internal ring, ligatured, and divided. The cord is next held up, while the arching fibres of the internal oblique and conjoined tendon are united behind it to the inner shelving margin of Poupart's ligament, to make a new floor for the inguinal canal. The first stitch should pick up first a good bite of the lower fibres of the internal oblique, then the fascial margin of the inner border of the internal ring just medial to the cord, and then the curved edge of Poupart's

ligament (fig. 2010). Subsequent stitches will pass through the lower edge of the conjoined tendon and the cremasteric fibres which spring from it above, and from Poupart's ligament below. The last should take the conjoined tendon and the inguinal ligament close to their insertion. Four to six sutures in all will be required, and all should be inserted before any is tied. When the row of sutures has been tied the cord is laid back on the bed of conjoined tendon, and the external oblique aponeurosis and skin are sutured in turn.

This operation has already been criticised in the introductory section, but such criticism is directed not against the pioneer who introduced

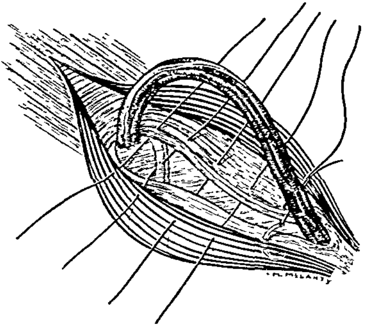

Fig. 2010.—Bassini's operation.

it, but against the men who follow him to-day. Bassini laid down the principles of free exposure of the canal and isolation of the sac up to its neck, upon which all subsequent operations are based. But the suture of conjoined muscle to Poupart's ligament, unless supplemented by something further, is useless and even harmful; useless because striated muscle forms very poor fibrous tissue, harmful in the early cases because the muscles are an essential part of the protective mechanism. That Bassini's operation in its historic form is followed by a high proportion of recurrences is familiar to any junior who sees the unselected out-patients presenting themselves to a surgical department, to any medical man who examines the employees of a large industrial concern, or to the expert adviser of truss societies. The practical experience of Gallie during the war should carry conviction. Speaking

of the large number of recurrences after the operation for hernia which were sent to him for repair he writes (*Brit. Journ. Surg.*, 1924, XII, 315): "A few which originally had been oblique hernias had recurred into the cord. In all probability the sac in these cases had never been completely removed. The majority, however, had recurred as direct hernias, irrespective of what the condition had been originally. . . . That hernias which were originally oblique should recur as direct hernias appeared to us as wanting explanation. . . . It may be that the weakening of the abdominal wall had resulted from the original operation in which the fascia transversalis may have been injured or the abdominal muscles destroyed by tight sutures. . . . In some the internal oblique muscle had been sutured to Poupart's ligament in front of the cord. In the majority, however, the internal oblique and the conjoined tendon had been sewn to Poupart's ligament behind the cord in an attempt to restore the obliquity of the canal. . . . In every recurred hernia operated upon, the internal oblique muscle had separated from Poupart's ligament throughout its inner half, and in some there was no evidence whatever that it had been sewn to the ligament. In not one instance, despite the fact that the records showed that the conjoined tendon and the sheath of the rectus had been sewn to Poupart's ligament with kangaroo tendon or catgut, did we find these structures together at the time of the second operation."

Bassini's operation stands in the same relation to hernia surgery that the carbolic spray does to aseptic technique: it should be kept in the same honoured place—the museum.

(*b*) *Bloodgood's rectus sheath flap.* The device of turning outwards a semilunar flap from the anterior sheath of the rectus to reinforce the inguinal canal has been advised and practised by many surgeons. It is most commonly referred to as Bloodgood's contribution to the elaborated and perfected form of Halsted's anterior method of repair which is often termed the Johns Hopkins operation. (W. S. Halsted, *Johns Hopkins Hosp. Bull.*, 1903, XIV, 208.) The rectus sheath flap is, however, not necessarily associated with anterior repair, and is used by many surgeons to reinforce the muscular sheets in a posterior reconstruction operation, much as the upper leaf of the external oblique is used in the Wyllys Andrews method. The diagram (fig. 2011) explains the method of cutting and suturing the flap.

While this method undoubtedly provides a strong aponeurotic flap, it leaves at the same time an unguarded area at the outer border of the rectus muscle, an area which is only protected by a thin sheet of transversalis fascia, and which is made wider by the suture of the

flap to Poupart's ligament. The likelihood of a direct hernia is therefore a real one.

Several surgeons (Downs, Schley, Blake) have advocated lateral displacement and suture to Poupart's ligament of the rectus muscle itself. Modern opinion tends to the view that striated muscle is a first-class ally when allowed to do its own job; displaced, transplanted, or pulled upon by stitches it is thoroughly unreliable. Gallie's remarks upon the late results of internal oblique suture apply with even more force to the operation of rectus displacement.

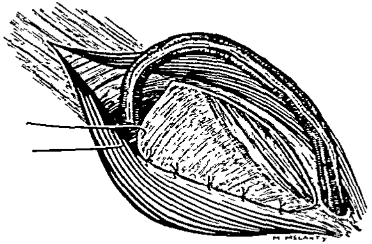

Fig. 2011.—POSTERIOR RECONSTRUCTION OF THE INGUINAL CANAL. BLOODGOOD'S RECTUS SHEATH FLAP.

(*c*) *Schmieden's operation.* Schmieden of Frankfurt has recently published a new method of posterior repair which, while it has not yet been widely tested, appears to be worthy of trial. After isolation and ligature of the sac in the usual manner, he pulls upon the cord and dissects the testis entirely free from the scrotum. The internal oblique and transversalis muscles are then split in the line of their fibres by blunt dissection about one inch above the internal ring (fig. 2012). The testis is drawn through this aperture, which is then narrowed by one or two catgut stitches to the exact size of the cord. The inguinal canal proper is completely obliterated by suture of the conjoined muscles to Poupart's ligament throughout their length. The testis is replaced in the scrotum, and the external oblique repaired over the cord.

Schmieden's operation is clearly an elaboration of Bassini's. It has two apparent advantages: first, that the cord, instead of passing from the inner margin of a stretched ring through muscles already weakened, but brought together by suture, now runs outwards from the peripheral part of the ring through a fresh incision in healthy muscles; and second, that the new inguinal canal is longer and more oblique than that which it replaces. In criticism it must be pointed out that

the inherent defects of the Bassini operation still apply to the closure of an empty canal, and that complete dislocation of the testicle may bring in its train sequelæ such as atrophy or hydrocele.

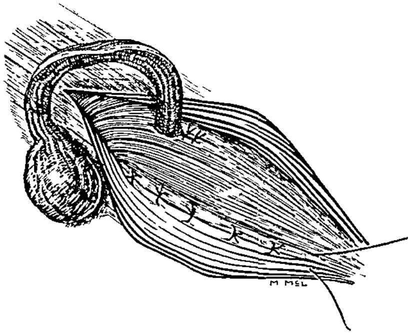

Fig 2012.—Schmieden's operation.

(6) *The anterior methods of repair.*

(*a*) *Halsted's operation.* The skin and external oblique aponeurosis are incised over the inguinal canal, and the external oblique flaps are dissected back to show clearly the cremaster and conjoined tendon. The cremaster is incised longitudinally a little above the centre of the cord. The hernial sac is then identified, separated by dissection from the structures of the cord right up to the internal ring, transfixed, ligatured, and cut across. During this step the other constituents of the cord, and particularly the vas, are left on the posterior wall of the canal, and indeed disturbed as little as possible. The muscular layers are then imbricated over the cord in the following manner: The lower flap of cremaster is first drawn up under the internal oblique and conjoined tendon by a series of mattress sutures of fine catgut passed through its free edge and then through the internal oblique muscle about an inch above its lower border (fig. 2013, top); the conjoined tendon is then sutured to Poupart's ligament by a series of interrupted stitches (fig. 2013, bottom). The operation is sometimes modified by incising the rectus sheath vertically to allow the conjoined tendon to be brought down to Poupart's ligament with less tension, or by turning a flap of anterior rectus sheath over the conjoined tendon. The operation

is completed by suturing the flaps of the external oblique aponeurosis with a similar overlap to the muscular layers, the lower leaf being drawn under the upper one (fig. 2014).

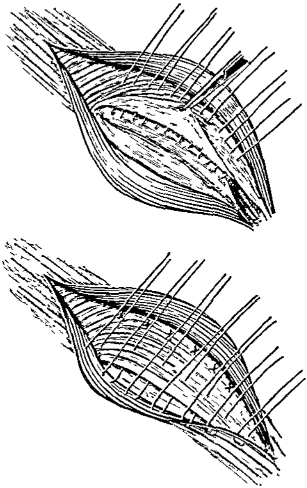

Fig 2013.—Halsted's operation.
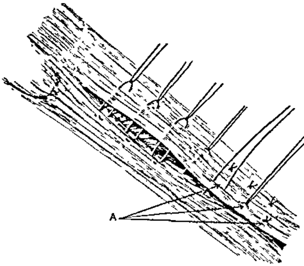
(*Top*) Suture of cremaster to deep surface of conjoined tendon in front of cord.
(*Bottom*) Suture of conjoined tendon to Poupart's ligament.

(*b*) *Ferguson's operation.* This operation is similar in its essentials to the Halsted operation, but, being based upon the author's belief that the chief cause of hernia is a deficiency of the internal oblique and transversalis muscles at their origin from Poupart's ligament, it concerns itself particularly with the outer half of the canal. The preliminary steps up to the exposure of the cord differ little from those of any other operation, except that Ferguson advised splitting the fibres of the external oblique up to a point opposite to the anterior superior iliac spine, in order to ensure a complete view of the deeper layers. The sac is dissected out and removed without disturbing the cord as in the Halsted operation. The internal ring is narrowed by the insertion of two or three catgut stitches through transversalis fascia anterior to the cord. The internal oblique and transversalis muscles are then stitched

to the recurved edge of Poupart's ligament, the sutures starting at the outer end and extending no more than two-thirds of the way towards the pubic spine, unless the hernia has been a particularly large one. The operation is finished by closing the external oblique aponeurosis with overlap, as in the Halsted operation.

I have already expressed my personal disagreement with the principle of anterior repair. I would repeat these sentiments by quoting Gallie once again, that " the time which is spent in preventing a hernia from getting out of the canal is much better spent in preventing it from getting into it." Both Halsted's and Ferguson's operations, by leaving the cord undisturbed, ignore the factor of medialward shift of the internal ring which is so potent a factor in recurrence.

Fig 2014.—HALSTED'S OPERATION. IMBRICATION OF THE EXTERNAL OBLIQUE APONEUROSIS. THE LOWER LEAF HAS BEEN DRAWN UNDER THE UPPER BY A SERIES OF SUTURES, THE INNER THREE OF WHICH ARE TIED AND CUT. (A) INDICATES THE FIRST THREE SUTURES OF THE SECOND LAYER WHICH ATTACHES THE UPPER LEAF TO THE NEIGHBOURHOOD OF POUPART'S LIGAMENT.



Ferguson's operation, indeed, by repairing the ring anterior to the cord, a repair that can only be done in its outer half, aggravates the shift still further. There is, so far as I know, no anatomical or clinical evidence whatever to support Ferguson's view that the origin of the deeper muscles from Poupart's ligament is deficient in hernia cases. During a clinical career extending over twenty-six years I have either opened or seen opened between 3000 and 4000 inguinal canals, but I have yet to see such an abnormality.

IV. SPECIAL PROBLEMS CONNECTED WITH INGUINAL HERNIA

(1) *Unusual difficulties encountered in the operation for Oblique Inguinal Hernia.*

(*a*) *The really large hernia.* An oblique hernia may, if neglected, attain truly massive proportions. Every surgeon has from time to time encountered such swellings, which vary in size from that of a grape-fruit to a Rugby football or even larger, and may extend as far

some of the contents will have returned to the abdomen, and the patient's general resistance will be improved.

Secondly, the great bulk of these large herniæ is usually made up of omentum, which has increased in size during its residence in the sac, and only a small part of it is intestine. The omentum can be ligatured at the neck of the sac and cut away, leaving a relatively small bulk of intestine to be returned to the abdomen.

Thirdly, local anæsthesia is entirely satisfactory and almost entirely safe for such operations; in the type of subject under discussion, it is usually to be preferred.

Fourthly, the operation may be heroic, but it can be interrupted at any time, and should be if the condition of the patient gives rise to anxiety. I have on occasion done these large hernia operations in three stages, all under local anæsthesia, a week or ten days intervening between each: First, exposure of the sac, and ligature and excision of omentum; second, freeing from adhesions and return to abdomen of loops of intestine, followed by closure of the neck of the sac by a simple purse-string suture; third, proper isolation and ligature of neck, removal of remainder of sac, and closure of hernial canal.

The operation will follow the general lines of the standard one with such modifications as are imposed by the size of the swelling and the condition of the skin (a wide ellipse may be required to excise an ulcerated area). When the cremasteric layer, here consisting of fat and fibrous tissue, has been reflected off the cord, the sac should be opened immediately and its contents dealt with from inside; only when it has been emptied and closed at the internal ring should any attempt be made to separate it from the cord. When the sac has been excised, it is rarely practicable, in my experience, to attempt radical cure. The external oblique aponeurosis is like tissue-paper, Poupart's ligament runs along the lowest part of the deficiency as a narrow strip which

as the knees of the patient. The skin over them is thinned, eczematous or even ulcerated, and the penis is entirely buried by the swelling, so that the urine dribbles through a small depressed orifice, excoriating the surrounding area. The patient, unable to take any exercise, is fat, emphysematous, and constipated, and usually shows in addition the signs of myocardial degeneration.

Such men present a heartbreaking surgical problem, but the majority have no desire for operation, and present no urgent symptoms rendering it necessary. Considering the technical difficulties and the risks of such a step, this is indeed fortunate. Some can be made comfortable and allowed a certain amount of activity with a bag truss; many are necessarily bedridden.

Occasionally, however, the surgeon is urgently requested to undertake operation in such a case, or may feel obliged to advise it himself. The patient may be younger than usual, and some stimulus, a new sweetheart, the prospect of a job, or even the desire to cease dependence upon others, impels him to demand a chance of leading a more active life. Recurring attacks of partial intestinal obstruction may force the surgeon's hand.

The technical difficulties in such a case are that the operation itself is one of considerable magnitude. that all structures are so distorted and interlaid with fat that the usual landmarks are barely recognisable, that when the contents of the sac have been freed there is often insufficient room in the abdominal cavity to allow their reduction, and that, even supposing the contents have been reduced and the hernial sac tied off, the structures of the inguinal region have been so distorted and atrophied by pressure, that any form of satisfactory repair is impossible. The risks are even more apparent—those of a really severe and lengthy operation on a patient whose cardiac, renal and respiratory systems are only just adequate for a quiet existence.

The surgeon faced with such a problem may reflect whether his difficulties cannot be lessened by attention to some of the following points:

Firstly, in any such case, the greater part of the coverings of the swelling. of the contents of the sac, and of the structures in the abdomen into which those contents must be returned, consists of fat. If the patient is kept in bed with the foot of the bed raised on blocks 14 inches high for six weeks before operation, purged regularly, and placed on a really strict reducing diet, not only will the size of the swelling to be tackled be reduced about 50 per cent, but

some of the contents will have returned to the abdomen, and the patient's general resistance will be improved.

Secondly, the great bulk of these large herniæ is usually made up of omentum, which has increased in size during its residence in the sac, and only a small part of it is intestine. The omentum can be ligatured at the neck of the sac and cut away, leaving a relatively small bulk of intestine to be returned to the abdomen.

Thirdly, local anæsthesia is entirely satisfactory and almost entirely safe for such operations; in the type of subject under discussion, it is usually to be preferred.

Fourthly, the operation may be heroic, but it can be interrupted at any time, and should be if the condition of the patient gives rise to anxiety. I have on occasion done these large hernia operations in three stages, all under local anæsthesia, a week or ten days intervening between each: First, exposure of the sac, and ligature and excision of omentum; second, freeing from adhesions and return to abdomen of loops of intestine, followed by closure of the neck of the sac by a simple purse-string suture; third, proper isolation and ligature of neck, removal of remainder of sac, and closure of hernial canal.

The operation will follow the general lines of the standard one with such modifications as are imposed by the size of the swelling and the condition of the skin (a wide ellipse may be required to excise an ulcerated area). When the cremasteric layer, here consisting of fat and fibrous tissue, has been reflected off the cord, the sac should be opened immediately and its contents dealt with from inside; only when it has been emptied and closed at the internal ring should any attempt be made to separate it from the cord. When the sac has been excised, it is rarely practicable, in my experience, to attempt radical cure. The external oblique aponeurosis is like tissue-paper, Poupart's ligament runs along the lowest part of the deficiency as a narrow strip which cannot be trusted as a line of anchorage, and the conjoined tendon and adjacent parts of the deeper muscles are represented by pale scattered fibres in a mass of friable fat. In the more moderate herniæ, fascial suture may be undertaken, but in the worst ones the surgeon must be content with approximating such structures as he can find behind the cord with catgut sutures. Such an operation is not a radical cure in any sense; but the sac has been excised, its contents have been *returned to the abdomen, and the hernial opening* has been closed. A well-made belt with a large pad protecting the inguinal region will

allow the patient a degree of activity which, compared with his former state, means a new lease of life.

(*b*) *Sliding hernia.* The term "sliding hernia" indicates one in which increasing size has dragged down the adjacent parietal peritoneum into the hernial canal, and with it some neighbouring organ normally situated behind it. The hernial swelling therefore consists in part of a serous sac with the usual contents—omentum, or omentum and bowel—and in part of an organ which lies in the hernial canal beside the sac, that is, covered by its peritoneum on one aspect only. For practical purposes the organs found in a sliding hernia are either large intestine, the cæcum on the right and iliac colon on the left, or the bladder. The conditions under which these two organs are encountered in hernia surgery are so different that I propose to treat each separately.

The large intestine is usually encountered in the para-peritoneal situation in large, old-standing, oblique herniæ, very rarely in direct ones, and more commonly on the right side than the left. The condition is rarely recognisable with certainty on clinical examination; the swelling will not be completely reducible, but usually all that the surgeon is able to decide before operation is that the hernia is a large one of the type in which complete reconstruction of the inguinal canal will almost certainly be required. Even at operation the true state of things may not be immediately apparent. The sac when first picked up after reflection of the cremaster presents no unusual appearances except that it cannot be rendered empty, and the stripping of vessels at first proceeds according to plan; a point is reached, however, when it becomes apparent that the tissue under the left thumb is plain muscle and not peritoneum, and that the vessels which lie along it are not those of the cord, but the posterior cæcal vessels in the wall of the bowel. A surgeon encountering such a hernia at his first operation is almost bound for disaster; he will proceed with the methodical blunt dissection till he has either torn a hole in the cæcum or is brought to a standstill by furious bleeding from the cæcal vessels. One who has served his apprenticeship under supervision will be familiar by repeated handling of the usual herniæ with the feel and the white appearance of the normal sac, and the parallel arrangement and characteristic blanching and filling of the spermatic vessels as they are peeled off it. If he meets anything unusual—bowel which is slack yet will not reduce, peritoneum merging into a surface that is clearly plain muscle, or vessels that tear rather than separate—he will at once open the sac at some point where its wall is clearly not adherent, and see what he is dealing with. A sac should in any case be emptied, if possible before it is separated

from the cord; should this be impossible (the usual cause is adherent omentum), and provided that the surgeon is satisfied that omentum only lies in the sac, he may proceed to isolate it. In the case of any large oblique hernia apparently containing bowel which cannot be reduced, he should proceed with the greatest care, and in most cases open the sac first.

The bladder is not infrequently found as part of the wall of a direct inguinal hernia, but it may also come to lie as a relation of the inner side of the neck of a large, old-standing oblique one. The presence of the bladder in a hernia is often recognised upon clinical grounds by the history of double micturition. The patient discovers that after emptying his bladder he can produce a further flow of urine by some change of position, or by pressing on the hernia. If the surgeon follows the rule that the sac of a direct hernia should not be opened, and that that of an oblique one should be isolated, firstly half-way down the inguinal canal, then at the fundus, and lastly at the neck, he need have little fear of injuring the bladder. He will be warned by a sudden thickening of the neck of the sac at its inner side, and by the appearance of scattered muscle bundles and large veins, and will explore the bladder region by a finger in the neck of the sac.

Should the cæcum or bladder be wounded, the rent must be repaired at once with a double row of sutures. After a cæcal tear, the whole canal should be swabbed out with $\frac{1}{1000}$ flavine solution, and a corrugated rubber drain left in the wound for forty-eight hours; after a tear of the bladder, a catheter should be tied in.

The sac of a sliding hernia can only be removed where it is free from the extruded viscus—that is, in its more distal portions. Such redundant peritoneum should be cut away freely with scissors, the opening closed with a purse-string suture or a running stitch, and the remainder pushed back into the abdomen with the attached colon or bladder. In an old-standing hernia patient dissection may be necessary in the neighbourhood of the internal ring, to allow the whole swelling to be returned to the abdomen. The posterior wall of the canal must then be repaired over the weakened area by one of the methods of reconstruction described previously. Some writers advise that repair of a sliding hernia should be followed by some form of colopexy. The surgeon who believes that these pexy operations serve any useful purpose may be tempted to follow this advice.

The account of sliding hernia given above has necessarily dealt with a very large and important aspect of hernial surgery in a simplified way, and from an extremely practical outlook. The reader who wishes

to pursue the subject further will find it discussed in great detail in L. F. Watson's book *Hernia*, Chapters XXIII to XXVII (London, Henry Kimpton, 1924).

(*c*) *Interstitial hernia.* An interstitial hernia is an oblique hernia in which the disposition of the peritoneal sac departs from the normal course of the cord and funicular process. The whole sac may be so displaced; more often the abnormality is an aberrant diverticulum from a sac which lies in the fascial sheath of the cord, the two communicating with the abdominal cavity by a common opening. An interstitial hernia is usually an accompaniment of late or imperfect descent of the testicle; but it may also be acquired, the result of abdominal pressure distending the proximal part of a sac whose distal portion is blocked by adhesions or the pressure of a truss. Three varieties are described:

(1) *The Properitoneal*, where the sac extends within the abdominal wall between the peritoneum and transversalis fascia. The properitoneal sac may pass inwards towards the bladder and pubis, or outwards parallel to Poupart's ligament.

(2) *The Intra-muscular*, lying between the external oblique aponeurosis and the internal oblique muscle; such a hernia may extend laterally, parallel to Poupart's ligament, or directly upwards.

(3) *The Superficial*, in which the sac, after leaving the external ring, turns back over the abdominal wall instead of reaching into the scrotum.

Of the three varieties, the first rarely gives rise to any symptoms or physical signs whereby it can be recognised. The second and third present swellings with the main characters of an inguinal hernia, but lying in an unusual site. The intra-muscular hernia can usually be diagnosed by the manner in which its outline becomes obscured when the external oblique muscle is put into action. The superficial type is occasionally mistaken for a femoral hernia.

Except in strangulation, when the concealment of an obstructed loop in such a diverticulum may cause some confusion at operation, these interstitial herniæ are of little more than academic interest. The surgeon who dissects the inguinal canal layer by layer will have no difficulty in recognising such abnormalities, even should he not suspect them beforehand, or in dealing with them when he meets them.

(*d*) *Recurrent hernia.* The operative treatment of a recurrent inguinal hernia differs from that of a primary one only in the added

difficulty in establishing the planes and exposing the defect which is inevitable where a previous operation has been performed. The guiding principle of all repair surgery—to expose structures where they are normal—governs the method of approach.

The cutaneous scar of the previous incision is first outlined with an elliptic cut, and this cut is deepened through the fat above and below the operation area till the aponeurotic layer is exposed. When this layer has been defined all round, the ellipse of fat and skin is cut away with a sweep of the knife. A little trimming with knife or scissors will then define the old suture line in the external oblique. The aponeurosis is next slit with a knife in the line of the old incision, but just above its upper end, in order to open the subaponeurotic layer where it is unscarred. The closed Mayo scissors are pushed into this slit and worked down between the aponeurotic and muscular layers till the ring is reached ; when the plane has thus been freed, the slit is extended down through the old scar into the external ring, and the flaps are turned up and down.

The nature of the subsequent steps will depend entirely upon the condition which is now disclosed, and the decision of the surgeon will be based upon the same principles which guide him in operating upon a primary hernia. In a surprising number of cases there is an almost virginal inguinal canal, containing a complete congenital sac ; it is clear that the previous operator has either missed his bearings, as may easily happen if the repair was done during infancy, or has been forced by some anæsthetic difficulty to abandon the operation uncompleted. In the majority, however, the hernia has recurred as a direct one, and some form of plastic reconstruction is required.

(2) *The localised form of Direct Hernia.*

This type of hernia, which is admittedly a rarity, and which I have not found described in any of the works I have consulted, is referred to on page 3620 ; I have met perhaps half a dozen instances. The hernial opening is medial to the deep epigastric artery, but is not a giving way of the whole region, but a circumscribed aperture with sharp margins in a firm posterior wall. The sac is tubular and emerges through the external ring beside the cord. The hernia is therefore believed to be oblique and an operation is undertaken on this diagnosis; only when the cremaster has been reflected does its nature become clear. Whatever the origin of the defect, its repair is an extremely simple matter, requiring no more than excision of the sac and approximation of the margins of the opening, either by silk or by a simple pedicled aponeurotic strip cut from the upper leaf of the external oblique.

(3) *Methods of approach to Inguinal Hernia other than through the Inguinal Canal.*

(*a*) *Through the abdominal cavity.* Both Annandale and Lawson Tait formerly practised an approach to the inguinal canal by a mid-line laparotomy incision. More recently G. P. La Roque (*Surg., Gyn. and Obst.*, 1919, XXIX, 507) advised opening the peritoneal cavity well above the internal ring by splitting the internal oblique and transversalis muscles about an inch above their lower margin, after exposing the sac in the inguinal canal. He inverts the sac into the upper incision and sutures across the peritoneum well above its neck, passing these sutures also through the new opening. It is difficult to see any real gain in either method. Plastic operations upon the peritoneum will avail little if the fibrous or muscular defences of the canal have given way, and inversion of the sac may damage the internal ring.

(*b*) *The extra-peritoneal approach.* Lenthal Cheatle (*B.M.J.*, 1921, II, 1025), and more recently Professor A. K. Henry (*Lancet*, 1936, I, 532), have advocated approach to the inguinal canal by the extra-peritoneal route, through a mid-line incision. By pushing the peritoneum back from the transversalis fascia, the back of the inguinal canal and the internal ring is reached with extraordinary ease and rapidity. Removal of the sac from the inguinal canal is obviously a much more intricate problem, and the surgeon who is familiar with the prolonged and careful dissection which is required to separate sac from cord in the usual operation, may feel alarmed at the prospect of this "blind extraction." Both surgeons admit the difficulty: Cheatle advises that when separation is not easy, the sac should be divided and its distal part left in the canal, while Henry states that the dissection is made comparatively simple if an assistant keeps the cord taut by holding down the testis in the scrotum.

Whether the extra-peritoneal method will prove of real value in the surgery of inguinal hernia cannot be decided till it has had a more extended trial. Henry has probably contributed more advances of real importance to technical surgery, in the way of new routes of approach planned upon anatomical lines, than any other surgeon in active practice to-day. His recommendation alone should ensure the method a trial, and his claim that the internal ring and posterior wall may be repaired more readily from within than without, is, on the face of it, a reasonable one.

CHAPTER III

Femoral Hernia

A review of the accepted teaching of anatomical text-books is even less necessary in this section than in that devoted to inguinal hernia. There would be no femoral hernia problem were the lower limb fixed, like the upper, entirely to the outer framework of the trunk. Unfortunately the whole group of the flexor muscles of the thigh extends well into the abdomen, indeed above it into the thorax. The abdominal musculature is everywhere firmly anchored to the bony and ligamentous boundaries of the cavity, except where this troublesome group of muscles must be allowed exit. The shallow trough in which they run is bridged by Poupart's ligament, which is anchored to its two margins, the anterior superior spine of the ilium and the spine of the pubis. The anchorage at the inner end is continued by Gimbernat's ligament which, separately named, can only be viewed as the deeper part of Poupart's ligament, fanned out for more secure attachment. Gimbernat's ligament, then, fills up the outer angle of the flexor trough; it is roughly an equilateral triangle, whose apex is at the pubic spine, one of whose margins is continuous with Poupart's ligament, another attached from the pubic spine along the inner end of the ilio-pectineal line, the third free and facing outwards towards the sub-Poupart trough. On the ilio-pectineal line, Gimbernat's ligament is sandwiched between two other structures of surgical importance (fig. 2015), the origin of pectineus below (an origin which is linear and tendinous and not wide as illustrated in books on osteology; the tendon of origin is known as Astley Cooper's ligament) and the insertion of the conjoined tendon on its pelvic side.

Poupart's ligament is secure enough above—it is part of the abdominal musculature; below, its security appears to depend on faith and fibrous tissue (fig. 2016). The fascia lining the abdomen, transversalis fascia in front and iliac fascia behind, sweeps round in a continuous sheet, gaining attachment to Poupart's ligament as it passes behind it; the same fascia is, however, continued into the thigh as the sheath of the iliacus and psoas, so that Poupart's ligament is fixed to these muscles where they pass under it by connective tissue

bands. Nerves and muscles pass into the thigh. The nerves, arising from the vertebral canal, are always behind the fascia ; but the vessels, coming from trunks which lie on the vertebral bodies in front of the posterior muscles, are in front of their fascia, and hence, reaching a point where this fascia sweeps up behind Poupart's ligament to reach the anterior wall, they must push through it, carrying a fascial coat on their walls. This coat is the femoral sheath.

In the thigh the fascia iliaca becomes the deep fascia covering the flexor group of muscles to the outer side of the femoral vessels. A new fascial layer, that over the pectineus, appears in the thigh behind the vessels, and this sheath, known here as the pubic fascia, is attached to

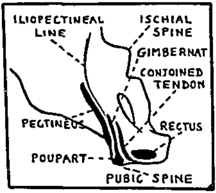


Fig 2015.—Diagram, modified from Frazer's *Anatomy of the Human Skeleton*, to show attachments to the ilio-pectineal line.

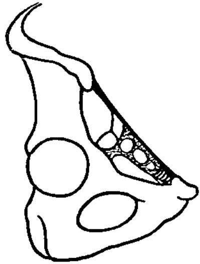

Fig. 2016.—The fascial attachments of Poupart's ligament.

the femoral sheath in front, and through that to Poupart's ligament, and behind dips down in the interval between the pectineus and psoas to become firmly fixed to the ilio-pectineal eminence and the capsule of the hip-joint. This band, the connective tissue web extending back from Poupart's ligament, embracing the femoral vessels, and anchored behind to the framework of the pelvis, is the only one stout enough to be demonstrable by ordinary methods of dissection.

The two fascial layers in the thigh, the iliac laterally and the pubic medially, blend below the point where the saphenous joins the common femoral vein. Above this point the iliac fascia stops short in a sharp border which bounds the saphenous opening laterally, and then sweeps above it as the falciform or Hey's ligament, to join the inner end of Poupart's ligament, and through it Gimbernat's ligament;

the pubic fascia has no real margin but passes behind the vessels as has been described. The saphenous opening is bridged by a thin sheath —the cribriform fascia. A sketch of the sub-Poupart trough, and one of the attachments to the ilio-pectineal line is appended (figs. 2015 and 2016).

When these somewhat indefinite moorings of Poupart's ligament are considered, it might be expected that the abdominal contents would force their way under it into the thigh at almost any point, if propelled by repeated pressure. Such is actually the case; herniæ are seen outside, behind, and in front of the femoral vessels, and even through Gimbernat's ligament and between the pectineus and its fascia. All these are, however, rarities, seldom encountered in the ordinary surgical lifetime. A sub-Poupart hernia is nearly always through the crural canal—that is, a femoral hernia.

The crural canal is described as the innermost of three compartments of the femoral sheath—the arterial, the venous, and the crural canal. Its walls are the same fascial layers. Above, it has an opening bounded by Gimbernat's ligament medially, Poupart's ligament in front, the origin of pectineus behind, and the femoral vein laterally; the opening is sealed from the peritoneum by a fibrous sheet, the septum crurale. Below, its walls converge to join the femoral sheath. The contents of the canal are said to be fat, a lymph gland, and lymph channels running from the deep femoral to the external iliac group of glands. Thus far is orthodox teaching; but the conscientious demonstrator in the dissecting-room who is asked by the student to show him the crural canal is torn between his desire to support authority and the faith of the young, and his inability to produce anything convincing. It is more rational to regard this channel, with Keith, as a hypothetical space and a dissecting-room product—in reality the inner half of the venous compartment. The circulation of the thigh during activity may be increased anything from ten to twenty times, and to carry this augmented flow of blood the femoral vein must have room in the rigid sub-Poupart trough to increase its cross-section. Under such conditions it is probable that there is no crural canal; after death there is no circulation and the crural canal appears.

These anatomical and functional considerations have a very definite bearing upon the surgery of femoral hernia; if accepted, they necessarily imply certain conclusions which must govern the principles upon which operations are designed:

1. That the hernial opening begins, and the neck of the peritoneal sac lies, at the inner edge of Gimbernat's ligament. This level is well

above Poupart's ligament and still more remote from the saphenous opening. The sac cannot, therefore, be controlled up to its neck by any form of truss, nor can its junction with the parietal peritoneum be reached by any approach from below, except after an amount of traction and forcible separation of fibrous planes which is more likely to invite recurrence than is high ligation to prevent it. For the same reason the crural opening cannot be closed securely and safely at its commencement by any method of suture from the thigh.

2. That Poupart's ligament depends for its security less upon demonstrable bonds than upon a wide fascial anchorage. Any avoidable damage to these fibrous planes, such, for instance, as that caused by dragging a femoral sac from the thigh to the abdomen through the crural canal, will, on the face of it, induce a weakness for which subsequent repair may not adequately atone.

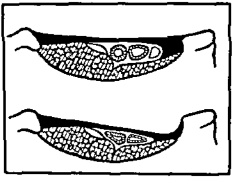

Fig 2017.—To illustrate the effect of suturing Poupart's ligament to the ilio-pectineal line, or pegging it to the bone.

3. That the crural canal is a sub-compartment of the venous channel, and Poupart's ligament is the selvedge of the anterior abdominal muscular sheet. Any method of closing the hernial channel which depends upon fixing down Poupart's ligament is unsound on both counts, because it must compress the vascular tunnel in an antero-posterior direction, and because the fixation must in time yield to the continual play of the abdominal muscles (fig. 2017).

THE ÆTIOLOGY OF FEMORAL HERNIA

Hamilton Russell, whose exposition of the congenital nature of oblique inguinal hernia has formed the basis of contemporary teaching, has endeavoured to apply the same theory to the formation of femoral hernia. (*Lancet*, 1906, II, 1197; *Brit. Journ. Surg.*, 1923, XI, 148; and *Surg., Gyn., Obst.*, 1926, XLIII, 147.) His view is that, with the growth of the limb bud during embryonic life, the vessels to the lower limb are drawn downwards from the abdominal cavity, and in some instances draw with them a pouch of peritoneum. In support of this hypothesis he states that the common directions in which a femoral sac extends after leaving the saphenous opening correspond to those of the main branches of the artery. The lingering of the congenital theory of femoral hernia to the present day is a tribute to Mr. Russell's eminence

as a surgeon, to his pioneer work in inguinal hernia, and to his persistent enthusiasm. No support whatsoever has been forthcoming from embryological research, from dissections of the fœtus, or from operation on the new-born child. A peritoneal pouch has never been seen in the limb bud, nor was Sir Arthur Keith (*Brit. Journ. Surg.*, 1924, XI, 455) able to find a femoral sac in five hundred human fœtuses examined. Russell counters this by saying that a number of sacs are found post mortem in adult bodies where hernia was unsuspected, and asseverates that from birth to adult life the vessels to the lower limb are "making a slow progress downwards," and are therefore liable to drag down peritoneum with them. The first argument can be applied to anything; if we find gall-stones or duodenal ulcers in people who have never had pain, does it mean that these lesions are congenital? The second suggestion is astounding; if we are to believe that the femoral artery increases in length by being pulled progressively out of the abdomen as a worm is pulled out of a hole in the lawn, and not, as do all other structures in the limb, by multicentric growth, we must also believe that all its lateral branches are simultaneously creeping up to the abdomen along its walls, or we should find them in the adult pointing towards the head like the bristles on an ear of barley. Why, also, should the sac always lie to the inner side of the vein, and never accompany the artery? To the best of my belief the majority of surgeons in Britain and on the Continent accept femoral hernia as perhaps the most typical example of an acquired defect, and find no foundation for the congenital theory.

Such a summary may be too sweeping. Femoral hernia is occasionally encountered in childhood, where the factors causing an acquired yielding would seem to be lacking; but it is sufficiently rare (two in three hundred in my own experience), and almost unknown under the age of ten. Two causes appear to be operative—repeated strain, and the development of fat which presumably weakens the fibrous planes of the femoral region.

Femoral hernia is less common than inguinal, but whereas in men the proportion is about one femoral hernia to twenty inguinal, in women it is about one to three. Comparing the sexes, femoral hernia is about six times as common in women as in men, but this disproportion is almost entirely accounted for by its prevalence in women who have borne children; the incidence in those who are childless is about the same as it is in men. Femoral hernia is then very largely a labour casualty, and the conditions under which civilised women bear their children, involving as they do a femoral vein emptied by rest and the

recumbent position, and abdominal contractions more prolonged and severe than are ever seen in savages or animals, seem ideal for its production.

PATHOLOGICAL ANATOMY AND DIFFERENTIAL DIAGNOSIS

The coverings of a femoral hernia, beyond the skin and superficial fascial layers, should be cribriform fascia, fat in the saphenous opening, femoral sheath, fat in the sheath, septum crurale, extra-peritoneal fat and peritoneum—that is, alternate layers of fat and fascia. Needless to say, these layers can never be demonstrated, but it is notorious that many, a most puzzling number, will be divided in turn before the actual sac is reached. The operator would be wise to remember the aphorism that "a femoral hernia has as many layers as an onion." In any case, the coverings form a bulky mass, usually exceeding considerably the sac in their midst; this bulk accounts for the well-known fact that, while the contents of a femoral hernia may be reducible, a palpable lump nearly always remains in the saphenous opening after reduction.

The size of the sac and its coverings varies greatly, and tends to increase with the duration of the hernia; the neck, however, lying in a rigid channel except for the wall of the vein on one side, tends to remain a tube of small diameter. The inguinal sac as it enlarges keeps its resemblance to a glove finger; the large femoral sac becomes a balloon on a stalk. The swelling appears at the saphenous opening, and as it enlarges tends to remain there. If it alters direction it is usually to turn upwards over the inner end of Poupart's ligament. While many fanciful reasons have been given for this line of extension, the probable explanation is that it follows the same mechanical laws *as a ribbon of tooth-paste forced through an accidental and curved* opening in the tube. A femoral hernia first comes downwards, and then forwards, because further downward expansion is blocked; each further portion as it is extruded must follow the same course, one which will push the head of the mass directly upwards.

The differential diagnosis of a femoral hernia will depend, in the main, upon whether it is reducible or not.

The majority met with in a surgical out-patient department are irreducible but quite symptomless. The sac contains nothing but omentum, which in course of time has become thickened, fibrous and adherent to the peritoneal lining; at the same time the outer coverings have increased in bulk by further deposition of fat. Such a swelling presents no symptoms, and no signs apart from those of a rounded elastic tumour in the inner half of Scarpa's triangle. It must be dis-

tinguished from an enlarged inguinal lymph gland and a lipoma—the only conditions which it really resembles. The essential point is to determine that the swelling has a neck, and that this neck passes directly backwards just below Poupart's ligament and just to the inner side of the femoral vessels. *When the lump is grasped and moved* about this can usually be demonstrated with ease. A lymphatic gland lies in the fascial plane, and is linked to other glands in that plane; it can be moved to a limited but approximately equal extent in all directions. A single enlarged inguinal gland is, in any case, unusual. A lipoma moves with the subcutaneous fat, and can be lifted off the deep fascia. A femoral hernia can only be moved in circles round its point of deep attachment—like the joy-stick of an aeroplane; in most cases the "stalk" itself can be felt.

A reducible femoral hernia may be quite clearly a hernia; that is, it reduces, not immediately, but after a little manipulation, and it returns, not immediately, but after three or four coughs. Both reduction and reappearance are accompanied by the characteristic gurgle of intestine, and the swelling, when distended, is resonant to percussion. The only difficulty in such a case arises when the sac overlies the inner end of Poupart's ligament, and the diagnosis has to be made between a femoral and an inguinal hernia. The decision will depend upon the relation of the swelling to the pubic spine, and whether, after reduction, it reappears above or below Poupart's ligament. It is often said that an inguinal hernia lies *above* the pubic spine; it usually lies *over* it. But in inguinal hernia it is only possible, by pushing from below and lateral to the swelling, to place the finger on the pubic spine, while in femoral hernia the spine can only be reached above and medial to it. After the hernia is reduced, a finger should be placed on the inner end of Poupart's ligament, and kept there while the patient coughs; it can then be determined if the swelling reappears below, that is, from the crural canal, or above, from the inguinal canal.

Two reducible swellings in Scarpa's triangle, saphena varix and psoas abscess, are often mistaken for femoral hernia; the first mistake is harmless, the second may have tragic consequences. Neither has the true characters of a hernia—that is, there is no definite rounded outline to the swelling, nothing beyond gentle pressure is required to reduce it, and nothing more than the erect position to make it prominent. Neither is resonant or gives a gurgle when handled.

Saphena varix usually imparts a bluish colour to the overlying skin. The swelling is rarely larger than a half walnut, and is so thin-walled that its outline cannot be clearly felt. It disappears not merely with

finger pressure, but when the patient lies down; when he coughs, a fluid thrill, like that in a varicocele, can be felt over it.

To suggest that a psoas abscess may be mistaken for femoral hernia may sound ludicrous; but the mistake is made repeatedly by surgeons of the highest standing, and not merely in the out-patient department, but when the patient has arrived at the operating table. It must be remembered that those who are seen with these dissecting psoas abscesses are not the text-book cases of spinal caries which are demonstrated to students, i.e. children and young adults with emaciated faces, barrel chests, and a prominent kyphos; they are old men and women in whom the disease assumes the quiet subperiosteal form, without destruction of bone, without a degree of pain suggesting anything more than "rheumatics," without even limitation of spinal movement in excess of that which accompanies osteo-arthritis. They may come to hospital for the first time to report an inguinal swelling that has appeared in the last few weeks, and give no history of backache. The wary surgeon, seeing a reducible swelling below Poupart's ligament, will be struck at once by the absence of that definition typical of a femoral sac, which usually suggests a rubber ball under the skin. A small psoas abscess, the most deceptive kind, will lie lateral to the femoral vessels; a larger one, having ruptured the psoas fascia, may be medial, but will be slack and diffuse, suggesting at once a cold abscess. Confirmation will be obtained by the demonstration of a second swelling in the iliac fossa, and the proof that material "reduced" from one merely expands the other.

OPERATIVE TREATMENT OF FEMORAL HERNIA

The operations for femoral hernia fall into two natural groups: the low operations performed through the saphenous opening, and the high operations, through the inguinal canal.

Whereas it is possible in inguinal hernia to name many of the standard operations after the surgeons who first described or popularised them, in femoral hernia such a method is valueless, for the methods have grown up rather than been introduced. The low operation is as old as surgery itself, for the first instinct of mankind is to tackle any problem in the most direct and simple manner, and only later to think of improvements; the only variations are in the methods advised to close the canal, and these merge into one another by infinitely small gradations. The high operation through the inguinal canal is usually named after Lotheissen, but even a perfunctory search of the literature shows that the inguinal approach was suggested independently by more

than thirty surgeons in different countries, of whom Annandale of Edinburgh was undoubtedly the first. In any case the Lotheissen operation, which involved dragging an unopened sac through the canal, is not, or should not be, any longer performed by surgeons, and the modern operation has many parents but no name. By the modern operation I mean the modified inguinal one, because the high approach has steadily displaced the low one since about 1920, and is now performed almost exclusively in most clinics. The low operation is, however, very much simpler, and while perhaps less well founded it is by no means unsuccessful. It is difficult to get any figures upon the recurrences which follow it, but they are certainly not more than 10 per cent, and probably more like 5 per cent. It still remains the choice of the inexperienced or unassisted surgeon who is forced to operate, it is often advisable when time-saving and minimum interference are important, and it may be the best in many cases of strangulation. In any case its first stages are those of the modified high operation.

I. The Standard Operation

(1) *The skin incision.* In my experience the crease incision (see pages 3613 and 3626) advocated for inguinal hernia is equally suitable for femoral hernia, and preferable to one placed lower. The external oblique aponeurosis and the pillars of the ring are exposed as for inguinal hernia, and the lower flap is then dissected down below Poupart's ligament off the fascia of the thigh. The femoral swelling will appear covered by a thin layer of cribriform fascia, and when this is incised with a stroke of the knife, will extrude itself as a rounded fatty mass (see fig. 2018).

(2) *Exposure, opening, and division of the hernial sac.* While the lower skin flap is retracted, the fatty mass is held up between two pairs of toothed dissecting forceps, and boldly cut across with Mayo scissors. Reference has already been made to the number and confusion of the layers which cover a femoral sac; each should be pushed back towards the neck of the swelling by strokes of the closed scissors, and *the next layer be incised only when it is clearly displayed throughout* its extent. The sac itself will be recognised without difficulty when it is reached, except in a strangulated hernia; its outer surface is more definite, whiter, and more opaque than that of any covering layer, its *inner lining is smooth and glistening*; its absurdly small size in comparison to its wrappings is the only thing that may confuse the operator. The sac, when reached, should be cleared even more thoroughly than previous layers, till its narrow stalk disappearing under Poupart's

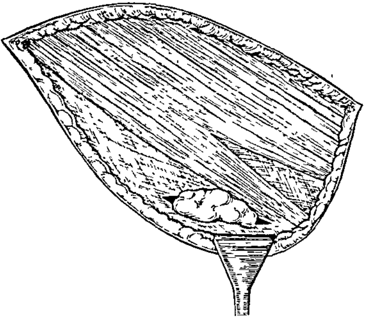

Fig. 2018.—The high (inguinal) operation for femoral hernia by the skin-crease incision. Reflection of flaps and exposure of inguinal region and hernial sac.

ligament is clearly displayed. The fundus is then opened, and any contents returned to the abdomen. Omentum, if thickened, may be ligatured and cut across; fringes of fat or loops of bowel should be returned by pressure of the tip of the finger or of a blunt instrument. Provided that the body of the sac has been emptied, any residual adhesions of omentum at the neck may be neglected at this stage. The sac is then clamped across just below its neck with a pair of hæmostats, and the remainder cut away (fig. 2019).

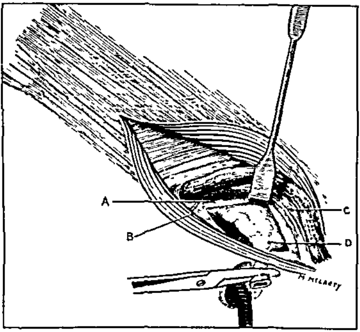

Fig. 2019.—The high (inguinal) operation for femoral hernia. The posterior wall of the inguinal canal has been incised and the neck of the hernial sac exposed from within.

B. Poupart's ligament.
C. Conjoined tendon.
D. Neck of sac.

(3) *Opening of the inguinal canal and exposure of the neck of the sac.* The inguinal canal is laid open by an incision in the external oblique extending into the pillars of the ring, the flaps are dissected back to expose conjoined tendon above and Poupart's ligament below, the cremaster is reflected, and the cord or round ligament is lifted from its bed to expose the posterior wall of the canal. The wall is incised with a knife about ¼-inch above and parallel to Poupart's ligament, taking care to avoid the epigastric vessels medially, and their pubic branch running along Poupart's ligament. The extra-peritoneal fat exposed in this incision is then pushed upwards away from Poupart's ligament with the finger or with small pledgets of gauze held in mosquito forceps, and will separate freely till the femoral opening is reached, when it is

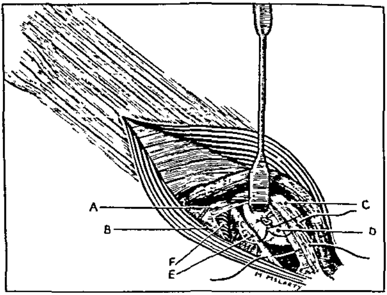

Fig. 2020.—The high operation for femoral hernia. The neck of the sac has been ligatured, one stitch has been passed from the conjoined tendon to Astley Cooper's ligament, and a second is being passed. A third will be required nearer the femoral vein.

F. Femoral vein.

tied by the emerging neck (see fig. 2019). This neck is quickly defined by blunt dissection, seized in a pair of stout forceps, and worked through into the inguinal incision. Here it is essential to disturb the fibrous surroundings of the neck as little as possible, but by gentle pulling while the tissues round it are slowly pushed down, aided at times by a pull in the reverse direction on the forceps which clamp the divided sac in the thigh, liberation will be accomplished with a minimum of trauma. The neck, when free, is pulled up into the wound, its inner side is examined for adherent bladder, it is opened, and any adherent omentum is cleared; finally, it is ligatured flush with the peritoneum, and cut away. There is no need to divide the neck just beyond the ligature; indeed, a long stump which will become fibrous tissue and form a gigantic septum crurale pushing the peritoneum well away from the crural opening is clearly an advantage.

(3) *Plugging the crural canal.*

(*a*) *With the sac.* Saunders Melville (*B.M.J.*, 1935, I, 467) divides the sac above the crural canal from within the abdomen, as described in section I*b* above, but first makes a small incision into the parietal peritoneum to see that the neck is empty. He does not remove the fundus of the sac. After closing the communication with the abdominal cavity by suture, he passes a pair of artery forceps into the sac from above Poupart's ligament, grasps the fundus, and inverts it into the abdominal cavity. Here it is obliterated and transformed by a few sutures into a flat plug, which he likens to the head of a rivet, and which effectually shields the weak area.

(*b*) *By auto-transplants.* Many substances have been advised: pedicled flaps of muscle from the pectineus or sartorius, of fat from the subcutaneous layers in the neighbourhood, or of the saphenous vein, divided low down in the thigh and curled up in the canal, and free transplants of fat, muscle, or costal cartilage.

III. The Low Operation

(1) *The skin incision.* The crease incision is entirely satisfactory for the low approach. More direct access is obtained by one immediately over the swelling, either below and parallel to Poupart's ligament, or starting half an inch above it and carried vertically downwards over the saphenous opening.

(2) *Isolation and ligature of the sac.* The methods for finding the sac which are advised in the standard operation are equally applicable to the low one. It is necessary, however, to isolate the neck as high as possible; this is done by gentle traction, while the fibrous tissues which surround it are snipped close to its wall with scissors and pushed up with their closed points. When it appears that the actual neck has been reached the sac is opened, emptied, tied off as high as possible and cut off. The stump is then pushed up the femoral canal out of sight.

(3) *Closure of the femoral ring.* It is unnecessary to discuss in any detail the many methods that have been suggested for closing the femoral channel from below, since, while their number is great, they differ in detail only and none is really satisfactory. The majority rely upon the suture of Poupart's ligament alone, or of Poupart's ligament and the falciform ligament, to the pectineus fascia. Marcy used a simple purse-string which entered Poupart's ligament near its inner end, and passed through Gimbernat's ligament, the pectineus fascia and as much of the femoral sheath as appeared to be safe, emerging again through Poupart's ligament near to its point of entry (fig. 2021, top).

Bassini inserted a series of interrupted sutures, the first two or three passing from Poupart's ligament to the pectineus fascia, and, before these were tied, another series from the falciform ligament to the same fascia (fig. 2021, bottom). Lockwood advocated a similar method but, by using a hernia needle and protecting the vein with a finger in the canal, he inserted the stitches into Cooper's ligament above. Other

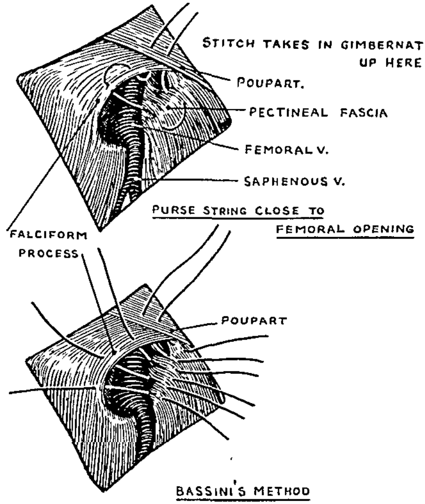

Fig 2021.—THE LOW OPERATION FOR FEMORAL HERNIA; CLOSURE OF THE CRURAL CANAL. (*Top*) THE PURSE STRING METHOD. (*Bottom*) BASSINI'S METHOD.

surgeons attempted to anchor Poupart's ligament directly to the pubic bone. Roux attained this end by driving a metal staple over the ligament directly into the bone, and Nichol of Glasgow by using a mattress suture passed through two holes drilled horizontally in the pubic ramus.

IV. THE EXTRA-PERITONEAL OPERATION

A. K. Henry, in the paper previously quoted (*Lancet*, 1936, I, 531), describes an extra-peritoneal approach to the femoral region, using a mid-line incision. The first case upon which he operated was

one of bilateral hernia in a girl. He writes: "I separated the recti at and below the navel, and stripped the unopened peritoneum from the sides of the bladder and from the pelvic wall. This at once gave a notable view of both hernial sacs, which stood out from the peritoneum like horns from a snail, and passed into the femoral rings" (fig. 2022). Henry delivered the sacs from the canals by blunt dissection, and ligatured them at their origin. He closed the canals by turning up a triangular flap of fascia, pedicled in front, from the pectineus muscle

Fig. 2022.—Henry's extra peritoneal approach for femoral hernia; to show the sac drawn out from the crural canal, the femoral vessels, and the cord passing out through the internal ring.

and suturing it to Poupart's ligament. He points out that a similar flap might be raised, and hinged behind at Cooper's ligament, which would avoid the possibility of a fresh hernia burrowing into the muscle itself.

Henry's exposure appears to be excellent, and through it any other method of repair could be carried out with equal facility. Thus the sac, if large, could be emptied from above and divided at its neck, avoiding the need to drag a bulky mass through the canal. The conjoined tendon could be sutured to Cooper's ligament with greater ease and with greater safety as regards the iliac vein than it can be through the inguinal incision.

CHAPTER IV

Rare Herniæ in the Pelvic Region

The varieties of herniæ through the abdominal wall are almost unlimited. Wherever vessels or nerves pass out, wherever muscles arise or are inserted, wherever fibrous intersections or septa occur, a pouch of peritoneum may be forced out by excessive, prolonged, or oft-repeated intra-abdominal pressure. It is quite beyond the scope of any work other than a monograph on hernia, to deal with these freak abnormalities in a degree of detail that would be of value to the post-graduate student. There have been, fortunately, surgeons who have devoted years of patient research to the collection of every possible fact relating to these uncommon conditions, and the result of their labours is available in any public library. These rare herniæ are, in any case, seldom seen unless they are strangulated, and no surgeon goes into the operating theatre to deal with an emergency primed with text-book maxims ; he is guided by general surgical principles, which his common sense and experience apply to the particular problem on hand.

Among such rare herniæ are those through Petit's triangle ; sciatic herniæ, above and below the pyriformis muscle ; perineal herniæ, which pass through defects in the pelvic floor at the point of exit of vessels or through gaps in the levator ani muscle ; and obturator herniæ. Of these only obturator hernia is reasonably common.

An obturator hernia passes through the obturator canal, the channel which is left at the upper part of the obturator foramen for the passage of the nerve and vessels into the thigh. The remainder of the foramen is closed by the tough thyroid membrane, which in turn is covered on its outer and inner aspects by the obturator externus and internus muscles. The pectineus muscle lies immediately in front of the crural end of the canal. The hernia is six times as common in women as in men, and in the former appears, like femoral hernia, to be the result of pregnancy.

The diagnosis of obturator hernia is seldom made on clinical grounds. Occasionally a woman complains of an intermittent swelling on the inner side of the thigh, and may state that its appearance is accompanied by gurgling sensations, disturbances of micturition, or pain down the

inner side of the thigh. Upon examination in such a case, an indefinite swelling may be seen in Scarpa's triangle, lying to the inner side of the femoral vessels, in the same place as a femoral hernia but much less definite in its outline. Palpation will reveal a bulge, which becomes less distinct when the muscles are contracted, and will possibly elicit tenderness. Vaginal examination may allow the actual opening to be felt, and will in any case disclose tenderness at the neck if a hernia is present. Pain referred down the branches of the obturator nerve is very characteristic.

In most cases the hernia is unsuspected till strangulation occurs, and even then no diagnosis is possible beyond that of intestinal obstruction of unknown origin.

Operation on an obturator hernia may be performed from the thigh or from the abdomen. The low approach is through a vertical incision. The interval between the pectineus and adductor longus muscles is separated, and if this does not give sufficient access, the pectineus is cut across close to its origin. This route allows direct exposure of the sac, but not reduction of gangrenous or adherent gut, high ligature of the sac, or satisfactory repair of the opening. For these reasons the abdominal approach is preferred by most surgeons. The sac is emptied, and can then usually be inverted into the abdomen. Satisfactory closure of the opening—a rigid aperture between ligament and bone which transmits nerves and vessels—is by no means easy. The simplest course is to plug the canal with a free transplant of fat, muscle or costal cartilage, before closing the neck of the sac. The inverted fundus may also be folded on itself by sutures to form a "rivet head," after the method recommended by Saunders Melville for femoral hernia (see page 3678).

CHAPTER V

Umbilical Hernia

The umbilicus is the scar left by the sloughing of the vascular pedicle whereby the fœtus obtained its nourishment in intra-uterine life. It marks the spot where, during the early stages that retrace the history of the vertebrate stock, changes of the most astounding nature have taken place. The human fœtus, when first recognisable, has an umbilical hernia so large that it would be more accurate to describe the whole as a hernia with a small embryo attached. This cavity, continuous with that of the abdomen and lined by the same peritoneum, contains the yolk sac and the fundus of the bladder known as the allantois. Yolk sac and allantois disappear early, and by the fifth week the umbilical diverticulum becomes occupied by the mid-gut loop, which has entered this " annexe " because too many other things are happening in the abdomen at the time to allow it room to develop. The mid-gut loop increases in length in this extra-abdominal pouch, and acquires that sharp demarcation between large and small gut which is marked by the ileo-cæcal angle. By the beginning of the tenth week, the abdomen once more has room for the whole alimentary canal, and the mid-gut loop returns to the main cavity through the umbilical orifice, now considerably reduced in size ; this return occurs remarkably *rapidly, and is complete by the end of the eleventh week. The* extra-abdominal cavity is now no longer required as such, the extra-cœlomic pouch of peritoneum disappears, and from the twelfth week till birth the umbilicus remains a well-defined ring in the abdominal musculature transmitting vessels only, two umbilical arteries and a vein. The reader who wishes to supplement this very brief résumé is referred to Keith's *Human Embryology*, or to Dott's article in the *British Journal of Surgery*, 1923, XI, 251.

At birth the umbilicus carries the umbilical cord and placenta. The skin is continued about half an inch along the cord, whose vessels are thenceforward covered only by Wharton's jelly and amnion. The cord being ligatured, that part outside the abdomen sloughs, and the scar is rapidly covered by a growth of skin from its edges. The umbilical vessels thrombose as far as the next functional channel within the

abdomen, and the clot in their lumen is rapidly converted into fibrous tissue by the ordinary processes of repair. During the first few weeks after birth, then, the umbilical scar consists of a firm ring surrounding a space filled by vascular organised clot, and is by no means strong. After six months the whole scar is a tough fibrous sheet, possibly the strongest spot in the abdominal wall.

In the adult the umbilicus marks about the centre, and the transitional point, of the linea alba. Above it the rectus muscles are separated by a space perhaps half an inch wide in the young and muscular, a space bridged by a felting of aponeurotic strands running chiefly in the transverse direction; below, the recti are in contact, and are divided only by a thin fibrous septum. On the posterior surface the umbilicus marks the meeting-point of three peritoneal folds, drawn out by the fibrous strands of the obliterated vessels as they are left behind in the process of growth; fat is often deposited in these folds, making them into pendulous fringes. The peritoneum at the umbilicus is fixed pretty firmly to the fascial planes.

TYPES OF HERNIÆ

Three separate varieties of herniæ occur at the umbilicus—the congenital, the infantile, and the adult—of which only one is truly umbilical. The congenital herniæ are not umbilical because they arose before, and prevented, the formation of an umbilicus, while the adult ones, except for a small minority, are not protrusions through the umbilical scar but above it—that is, they are para-umbilical.

I. Congenital Umbilical Hernia

A congenital defect remains at the umbilicus either when the *mid-gut loop fails to return to the abdominal cavity in the tenth week* of intra-uterine life, or when, though it has returned, the extra-cœlomic pouch of peritoneum fails to close. The failure may be of any degree, but for practical purposes two varieties may be described:

(*a*) *Complete exomphalos.*

In some cases the protrusion is ruptured during delivery, and the infant is born eviscerated. When this does not occur, the abdominal wall appears to be replaced by a greyish translucent dome, moulded into a series of knobs by the underlying viscera which can be faintly seen through it, the cord being attached to the summit. The abdominal wall lies well back in the flanks at the sides of the swelling, and the junction between abdomen proper and exomphalic swelling is marked by the sudden transition from pink skin to grey Wharton's jelly.

The coverings of the swelling are amnion, Wharton's jelly, and extra-cœlomic peritoneum. Its contents are in any case those parts derived from the mid-gut loop, the small intestine and proximal colon, with the addition in many cases of the greater part of the liver and some of the stomach and pelvic colon. These parts are seldom normal: the mid-gut loop is usually unrotated and unfixed, and the liver, unsubjected to the mutual moulding forces of intra-abdominal development, is a globular mass.

Exomphalos occurs in about one birth in ten thousand, and may be associated with other defects such as spina bifida. Two cases came under my care when I was a surgical registrar, and by one of those coincidences which are so common in surgery, both were admitted into the same ward in Guy's Hospital within six hours of each other. The first, which was under my late chief, Mr. R. P. Rowlands, was operated upon by me and later shown at the Royal Society of Medicine (W. H. Ogilvie, *Proc. Roy. Soc. Med.* (Clinical Section), Dec. 1921); he developed double inguinal hernia a year later, which was also repaired, and when last seen he was a healthy boy of twelve with a sound abdominal wall. The second case, under Mr. L. Bromley, already showed signs of peritonitis on admission and died shortly afterwards.

Treatment. Exomphalos is a surgical emergency, because the coverings of the swelling have no blood supply apart from that derived from the umbilical cord which ceases at birth. Unless the abdominal cavity can be closed with living tissues before it becomes infected, death is inevitable. Fortunately the abdominal wall is not deficient, but merely displaced.

An incision should be made rapidly round the junction of living tissues with Wharton's jelly, care being taken to preserve every bit of skin. The edges are undercut and turned out on each side for about an inch, to expose the underlying aponeurosis. The abdominal cavity is then opened at any point, and by rapid dissection with the finger, the coverings are separated from the viscera, and the edges of the mesoblastic defect made plain. The whole grey mass is then cut away, and a number of Ochsner forceps clamped on the edges of the abdominal wall on each side, and pulled together to approximate them. A series of tension sutures of salmon-gut guarded with rubber tubing are passed from side to side through skin and abdominal wall, and their ends are clamped. The edges of the defect are then approximated by interrupted sutures of No. 1 chromic catgut. If the condition of the child is entirely satisfactory, it is better to incise the rectus sheath for its full length on each side (see reconstruction operation under infantile hernia)

and to close the walls in two layers. The skin is approximated by a continuous suture, and the tension stitches are tied over a roll of gauze.

(*b*) *Congenital hernia into the cord.*

In this condition a peritoneal pouch of varying size extends from the abdominal cavity into the root of the umbilical cord, which may be expanded or of nearly normal appearance. The importance of such a hernia lies in the risk of a loop of bowel in the sac being included in the ligature applied at birth. Even if this does not happen, the same dangers remain as are inherent in exomphalos—that the coverings of the sac are non-viable. Every case should therefore be subjected to operation at the earliest possible opportunity. The method of repair will follow the general lines which have been laid down for the treatment of exomphalos, but the task of the surgeon is naturally a much simpler one, and the operative risk is less.

II. Infantile Umbilical Hernia

An infantile umbilical hernia is an acquired defect due to stretching of the newly formed cicatrix before it is strong. It is not therefore seen in the first few days after birth, and is very unlikely to appear after the sixth month. Some factor causing an increase in abdominal pressure, either constant or intermittent, is usually present; the infant on whom the blame cannot be laid for crying, coughing, phimosis, constipation, or tympanites is indeed a prodigy. The protrusion is rarely more than a small knob-like swelling the size of the last joint of a finger, and the fibrous ring of the abdominal wall proper is rarely stretched. These infantile herniæ are usually empty when the child does not strain, and very rarely become irreducible. They can be retained by a simple pad, and with this treatment the great majority are cured in twelve or at the most eighteen months. After this period repair by natural means is unlikely.

Treatment.

(1) *The incision.* Since the defect is a very small one in an abdominal wall that is perfectly sound up to its margins, only limited access is required. To remove the umbilicus is unnecessary mutilation, and thoroughly bad psychological if not surgical treatment, for it often leads to a pronounced sense of inferiority. A flap incision which preserves the cicatrix while giving access to the hernial opening should therefore be used. For many years I advocated a curved incision below the umbilicus, but I have now replaced this by a transverse one about an inch above it. If the surgeon studies the abdominal wall of a series of healthy young adults, both men and women, he will find three flexion

creases in almost constant positions; first, the suprapubic crease discussed in the inguinal section, which extends the whole width of the trunk; second, a shorter one with a more open curve about half-way between the pubis and umbilicus; and third, a straight one crossing the epigastrium a short distance above the umbilicus. The second is too low for an umbilical approach, the third is ideal (see fig. 1985).

The incision is carried down to the aponeurotic layer, and the lower flap is then dissected off the sac and surrounding sheath, to one or one and a half inches below the opening. The sac is pulled up, and the fibres which surround its neck are divided carefully with scissors or a sharp knife; as the fibres are cut, more and more sac will come out

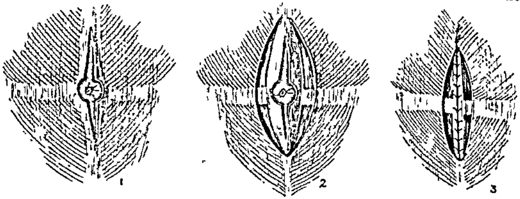

Fig. 2023.—THE RECONSTRUCTION OPERATION FOR UMBILICAL HERNIA.

1. THE SAC TIED OFF, THE OPENING ENLARGED BY INCISIONS UPWARDS AND DOWNWARDS IN THE LINEA ALBA.
2. THE RECTUS SHEATH OPENED ON EACH SIDE TO EXPOSE THE RECTUS MUSCLE.
3. THE TWO INNER MARGINS SUTURED TO FORM A POSTERIOR RECTUS SHEATH; COMMENCING SUTURE OF THE ANTERIOR LAYER.

till a good collar of peritoneum is free. The sac is then opened, emptied, tied off at its neck with a single ligature, and cut off.

(2) *Closure of the ring.* (*a*) In the usual hernia the defect is a small one, which can be repaired by simple suture. A purse-string of No. 1 catgut on a small, curved needle is first passed through the aponeurotic layer a few millimetres outside its margin; when tied, this buries the peritoneal stump and closes the hole. The weak area is further reinforced by three or four stitches, passed through the rectus sheath each side, which infold and bury the previous suture. The skin incision is closed with fine salmon-gut or Michel clips.

(*b*) If the ring has been stretched, a reconstruction of the rectus sheath is advisable. The opening in the aponeurosis is first elongated by incisions extending from its upper and lower margins into the linea alba for about $\frac{3}{4}$-inch. The rectus sheath on each side is opened along the whole length of this enlarged defect by a cut close to its margins, thus providing two aponeurotic edges, which, sewn together, constitute an anterior and posterior rectus sheath (fig. 2023).

III. The Umbilical Hernia of Adults

A small number of umbilical herniæ in adults are the reappearance of infantile ones thought to have been cured, which have again been rendered patent by the pressure of ascites or pregnancy. The great majority are acquired defects of the linea alba just above the umbilicus. They rarely appear before the age of twenty-five, but then become increasingly common till about the age of fifty, after which few new ones are reported. It will be noticed that this age span corresponds closely to the child-bearing period, and it is in women who have had children —usually many of them—that these herniæ are typically seen. Next to pregnancy, fat appears to be the most common cause, and in men about the only one.

An adult umbilical hernia is rarely seen when it is small, because it is then hidden in the general layer of fat covering the abdominal wall. When first noticed it is usually an oval swelling, with its greatest diameter in the transverse plane, and carrying the umbilical cicatrix below its centre. Such swellings usually increase rapidly in size. The skin over them becomes thinned. The umbilicus is stretched transversely so that its edges are approximated, and secretions collect and fester in its deeper parts. The fold below them becomes moist and eczematous. The margins are indefinite, because the surrounding fat does not allow an examining finger to reach the opening in the aponeurotic layer.

The sac is at first lined with peritoneum, but because the serous membrane is fixed to the abdominal wall at this point, further enlargement cannot be accompanied, as it is in other herniæ, by borrowing more peritoneum from that inside the abdomen. The coating splits and gives way in an irregular manner. In all the larger umbilical herniæ the sac wall is fibrous, much loculated, and lined by peritoneum at its neck alone. Hence adhesions form early, and the contents are reducible in part only, if at all. An adult umbilical hernia always contains omentum, usually transverse colon, and often some loop of jejunum.

Treatment. It has already been pointed out in the introductory section that a truss is generally useless in these cases, that strangulation is common and dangerous, and that operation is usually advisable even though the patients are poor subjects for any such ordeal. On these last grounds local anæsthesia will often be advantageous. The umbilicus should always be excised; the patients are old ladies, too fat and ugly for cosmetic surgery, too placid for complexes, and too eptic to allow the retention of infected loculi.

(1) *Reconstruction of the abdominal wall.*

In the case of small herniæ through a sound abdominal wall, such as those which represent the persistence of an infantile defect, the form of repair recommended for the larger herniæ of childhood should be adopted. The skin incision takes the form of a vertical ellipse, excising the navel.

(2) *Mayo's operation.*

The transverse overlap method, introduced by W. J. Mayo in 1893 for the radical cure of umbilical herniæ, is one of those rarities in surgery—a procedure that has remained unchallenged and unimproved since its introduction. It is founded upon the physiological concept that the aponeurotic planes of the mid-line of the abdomen are the tendon of insertion of the lateral muscles, and that the pull they resist, and therefore the strength of their fabric, is transverse. An overlap in the vertical plane is against the lines of stress, but one in the transverse plane is with them, and therefore secure.

(*a*) *The skin incision.* This is a wide transverse ellipse surrounding the umbilicus, extending up and down to include an amount of subcutaneous fat that may be considered redundant, and laterally, at any rate as far as the mid-point of the rectus muscles. The incision is immediately deepened to the aponeurotic layer, and the subcutaneous tissue is then dissected inwards off this layer till the fibrous neck of the sac is exposed.

(*b*) *Treatment of sac and peritoneum.* The whole mass of skin, fat, and hernia, is held up while the neck is gently cut round with knife or scissors (fig. 2024, 1). As the fibrous layers are divided, others appear and are snicked, till the peritoneal tube is entirely free of its aponeurotic sheath. The sac is opened at the same level—the neck, for here only is it likely to be free from adhesions. A finger or blunt director is introduced through the opening, which is then enlarged till the interior of the sac can be viewed, and the contents pulled out if sufficiently free; by working from neck to fundus, from free space to adhesions, this clearance can be done safely. Omentum may be ligatured and cut off; and intestinal loops must be freed, either by continuous dissection, or by snipping round the bits of sac which adhere to them and leaving them on their walls.

When the contents of the sac have been replaced in the abdomen, it is necessary to decide whether the peritoneum should be closed as a separate layer, or with the rectus sheath. If the opening is not more than 3 cms. across, the peritoneal

edges should be carefully dissected free from the abdominal wall on each side, and the hole closed by a running stitch. If the opening is larger, peritoneum and rectus sheath may be overlapped together.

(c) *Repair of the aponeurotic layers.* The opening in the linea alba is extended on each side by incisions carried outwards through all layers till they expose the inner border of the rectus; roughly circular before, it is now a transverse ellipse. The lower flap is

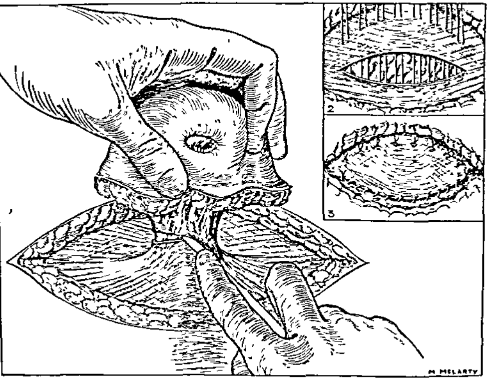

Fig. 2024.—MAYO'S OPERATION FOR UMBILICAL HERNIA.

drawn under the upper one by a series of mattress sutures of stout catgut. The first is passed through the upper flap near the mid-line and about two inches from its free edge from without inwards, a finger protecting the abdominal contents; then through the lower flap from within outwards, ½-inch from its edge, back through the edge of the lower flap; and once again through the upper one from within outwards, half an inch to the side of its point of entry (fig. 2024, 2). Other mattress sutures are similarly inserted on each side of the first, their distance from the upper margin of the opening decreasing as they near its lateral limits. When all these sutures are tied, the lower flap is pulled up under the upper as a wide tongue. The free

edge of the upper flap is now fixed to the aponeurosis below the opening by a continuous catgut stitch (fig. 2024, 3). When the recti are not widely divaricated, lateral cuts to their margins may not give flaps sufficiently wide for an overlap; in such a case the cuts may be extended further outwards through the anterior rectus sheath only, and this part alone be included in the more lateral of the overlap mattress sutures.

After attention to hæmostasis the skin and superficial layers are closed by the usual methods.

(3) *Very large herniæ.*

When the defect is so large that the Mayo overlap method cannot be performed without undue tension, or when, as sometimes occurs, the hernial opening is not one but two or three adjacent defects in the linea alba, the method of fascial suture should be employed.

IV. Epigastric Hernia

The ætiology of epigastric hernia seems to be identical with that of the para-umbilical herniæ of women, a protrusion through a chink in the felting of the linea alba above the umbilicus usually preceded by an extension of extra-peritoneal fat; the clinical picture is, however, entirely different.

Epigastric herniæ are usually seen in men under forty. They occur in the mid-line, about half-way between the xiphisternum and the umbilicus. They are usually small, not often exceeding a hazel-nut in size, and in many cases cannot be seen, but only felt. They are soft, giving the impression of a lipoma, and are often tender. Few of them give any impulse on coughing or contain anything which can be reduced, yet at operations the great majority are found to have a small peritoneal sac in the fatty lump. They chiefly attract attention because they cause pain—local pain in the lump, or indigestion of the duodenal ulcer type. This last has two possible explanations, the mechanical, suggesting interference with the contractions of the pyloric antrum during the later stages of digestion by a bud of gastric omentum nipped in the hernia, and the physiological, which accounts for the pain as a gastro-peritoneal reflex (see also Vol. I, page 207).

The defect should be repaired by a longitudinal reconstruction operation. It is always wise at the time to ascertain by inspection that the duodenum and gall-bladder are really normal, and to remove the appendix if this can be done without enlarging the incision.

use in the tough edges of an old scar, where they hold admirably. One layer of sutures will be used to approximate the edges, and a second may be inserted, taking a bite of the aponeurosis half an inch further out, a layer which reinforces the first and relieves it of all strain.

(3) *The repair of a really large incisional hernia.*

Defects are sometimes encountered which are so old and so wide that

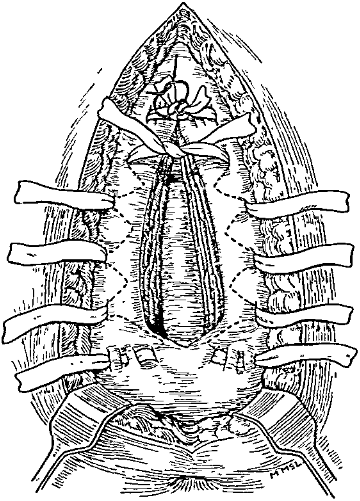

Fig. 2025.—Gallie's "many tailed" fascial transplant for large hernia.

no amount of pulling will approximate the edges. Here Rehn's dermal patch transplant (see page 3609), reinforced if necessary by fascial strips, will provide a way out of the difficulty. Gallie advocates large fascial transplants, cut like a many-tailed bandage, for the repair of these big openings. He writes: "As a rule two patches of fascia, five inches by three and one-half inches, can be obtained from the lateral aspect of a single thigh. The ends of the patches are then split into strips about one-quarter of an inch wide and by means of a fascia needle passed

through the edges of the ring as shown in figure 2025. If a second patch is needed it is laid edge to edge with the first and the two are sewn together with a fine strip of fascia lata threaded on a needle. At the ends of the opening, special precaution is taken to weave the tails into the edge of the ring so as to prevent a protrusion over the end of the fascial sheet. When all the tails have been drawn through the abdominal wall they are tied together, each to its fellow of the opposite side, and the edges of the opening drawn together as closely as seems safe. If they can be brought into contact without too much tension, so much the better, but if they cannot, the surgeon may rest assured that the deep side of the defect in the abdominal wall has been permanently closed off. Often it is possible, where the deep portion of the opening cannot be drawn together, to close the anterior rectus sheath with catgut or a suture of fascia and this shuts off the sheets of fascia from view and seems to be an advantage. Care should be taken to oversew the knots in the tails of fascia with catgut as these have a strong tendency to slip and untie when strain is put upon them."

PART XIX
PLASTIC SURGERY

by
T. Pomfret Kilner

PLASTIC SURGERY

CHAPTER I

Introduction and Technique

It is my intention to describe here those procedures which, thoroughly tried out on the mass of cases of disfigurement and deformity which formed the aftermath of the European War, have been found applicable to civil practice, and to add such developments as have been made in them; other procedures, of a more purely cosmetic nature but owing their origin to the same work, will also be put forward.

It would seem redundant in a work of this class to write any lengthy historical introduction; reference to almost any of the many books on special branches of this subject will provide such historical details. It will perhaps not be amiss, however, to remind readers that plastic surgery is a very ancient art, and that for centuries attempts have been made to reconstruct parts lost by accident or disease and to supply or correct features missing or deformed from congenital abnormality.

It would appear reasonable to summarise the development thus: plastic surgery was born centuries ago. It was still a puny ill-nourished child when the European War broke out. It received such abundant and concentrated nourishment in the post-War period that it grew with abnormal rapidity, and has now become a fully developed adult speciality which has absorbed many of those odd branches of surgery previously tackled only occasionally, and often in very indifferent manner by the general surgeon.

GENERAL TECHNIQUE

No branch of surgery teaches so clearly the necessity for gentle atraumatic handling of tissues. Every point of crushing is a point of potential necrosis. To avoid this, skin flaps or grafts are treated with the greatest respect, and as finger manipulation is less damaging than even the gentlest instrumental "handling," the instrumental aseptic technique of the orthopædic surgeon finds little place in surface work. Fine tissue hooks (fig. 2026), used not as retractors but as a means of holding and manipulating, are employed whenever possible. Forceps of the fine-toothed variety (Waugh's tonsil forceps) are employed where

hooks prove impracticable, but even these fine prehensile instruments are used with only the gentlest pressure on their points. When a skin graft or flap has to be handled as a whole, it is held by the fingers in a moist gauze swab. When grafts of deeper tissues—bone, cartilage or fascia lata—are being taken. aseptic technique and instrumental handling come into their own, and wound-edge protection to prevent contact with skin is employed.

Incisions

In an effort to minimise scarring, many different forms of incision have been tried. None has proved more effective in this respect than the clean cut produced by a scalpel with a really sharp edge applied at right angles to the skin surface.

In plastic work the position of an incision is frequently dictated by some pre-existing scar which calls for excision. Where this is not so, all incisions, particularly about the face and neck, are made to follow the

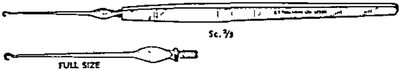

Fig. 2026.—Kilner's fine skin hook with detachable handle.

well-known skin tension lines described by Langer in 1861. (*Wien. Wchnbl.*, XVII, 20, K. Akademie der Wissenschaften, Wien, 1861, and *Roy. Soc. Med. Tracts*, Vol. 58, 19.)

Suture Materials and Suturing.

Skin suture material should be as fine as possible. It should not possess hygroscopic characters. Horse-hair, silk in one of its many forms, waxed or otherwise, and artificial silkworm-gut have all been tried, but the finest gossamer silkworm-gut has proved the most generally useful. Although only a small point, it is often a very important and yet overlooked one that fine suture material should always be dyed a distinctive colour, or the removal of sutures becomes a most difficult procedure. Overlooked buried pieces of colourless unabsorbable suture material have many times been discovered as the cause of disfiguring scar thickening or of persistent reaction in otherwise healed wounds.

There is no question about the advantages of having all such sutures attached to eyeless (atraumatic) needles, and it is only the expensive nature of these which would persuade the surgeon who had tried them to abandon their use on any occasion. They produce the minimum of trauma at the point of perforation, and as they pass through the skin

smoothly and without drag they call for less forcible holding of the skin by the forceps in the other hand. It stands to reason that the shorter the needle compatible with the work in hand the better, for there is bound to be some irregularity of action in drawing the needle through the skin, and the longer the needle the more this will show itself on the opening made. For most purposes eye-curved needles of sizes 3 and 6 are sufficient—the improved pattern needle of this class, which is slightly flatter in the shank, is less liable to slip round in the needle-holder. Where expense or other factors contra-indicate the use of atraumatic needles, similar fine needles of the eyed variety should be used. For heavier work curved needles size 18 are employed, while, where scarring is of secondary importance, e.g., in approximating edges of abdominal wall defects after removal of flaps, still larger needles (size 8) are used. For deep tissue approximation by catgut, fine half-circle needles (Fistula-fine 8) have proved useful, though occasionally here also an atraumatic needle may be indicated. There are situations where skin or mucous membrane edges have to be approximated and where sutures cannot be removed, inside the nose for example or in the reconstruction of the urethra, and in such situations the atraumatic needle threaded with fine catgut is essential.

Type of Suture

Endless varieties of suturing methods have been advocated, and each may find some special application. In skin suturing, however, the chief aim should be full-thickness skin-edge approximation, and any suture which will provide this in the particular situation under treatment should be used. In most situations interrupted skin sutures give the most perfect apposition. A nice judgment is required as to the distance apart to place these, more particularly so when some scar tissue must be left behind and the wound edges do not tend to fall naturally together as in fresh skin incisions. The end-on (vertical) mattress suture is, in my opinion, a most valuable stitch, for it gives perfect apposition of the deeper layers of the skin and at the same time ensures cuticular approximation. In its continuous form (see fig. 2027) it is probably the most frequently used suture.

Subcuticular sutures of absorbable material have their distinct uses for approximating deep tissues and for relieving tension on the skin suture line, but as a means of skin approximation they cannot be expected to give such good scars as those which give whole skin apposition. The subcuticular skin stitch, more correctly an intradermal stitch, has its special use in situations where it would be difficult to remove a large number of interrupted sutures or points of a continuous

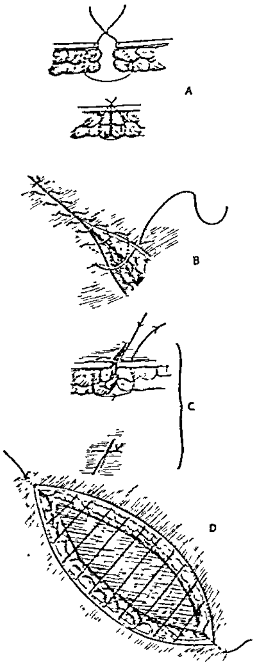

Fig. 2027.—Methods of suturing.

A. Interrupted suture taking full bite of deep tissues but entering and emerging close to the skin edge. A suture of this type gives broad wound-edge approximation with a minimal risk of stitch scarring.

B. Continuous end-on or vertical mattress suture. This gives broad wound-edge approximation and ensures accurate apposition of skin edges without inversion.

C. Interrupted end-on or vertical mattress suture.

D. Subcuticular or intradermal suture.

external one. In incisions in the retro-auricular furrow, for example, the ear has to be rolled forward for the removal of external sutures and this tends to drag open the newly-healed wound. An intradermal silkworm-gut suture in this region is readily removed from above or below without disturbing the lie of the ear. Again, in suture lines in the eyelids the repeated approach to the eye of scissors and forceps distresses the patient greatly, while the drawing out of an intradermal suture at the side causes very little discomfort.

In other situations it has been found that the intradermal suture often gives a false and flimsy epidermal approximation over a linear blood collection, a "blood blister" as it were, and the resulting scar, instead of being less obvious, is definitely wider. After all, the main object of the intradermal suture is to avoid scars from external sutures. If external sutures are placed near to the wound edge, are removed as soon as they have done their work (3–5 days), and if some dressing, e.g., collodion gauze, is then applied which will prevent early stretching of the scar, they provide the best and surest means available.

A very large number of other means of approximating wound edges has been suggested; some are impracticable in the general run of cases but each may find applicability to a special case.

Removal of Sutures

The removal of sutures may prove even more difficult than their insertion if damage to the newly-healed suture line is to be avoided. Fine non-toothed forceps of the type designed by McIndoe, and sharp-pointed scissors, thin at their ends, are essential. It is well to use short-shafted scissors, for there is no such thing as a perfectly steady hand, and any movement in the fingers is considerably multiplied at the end of a long instrument. Good lighting and, more particularly in young infants and nervous apprehensive adults, efficient assistance to steady the part are important. The removal of small fine sutures should be a carefully planned and deliberate undertaking and there should be nothing of "struggle" character about it. Preliminary sedation is seldom required except in small children who are frequently more troublesome than either young infants or adults. The importance of coloured suture material in this connection has already been stressed. Without it, it is the easiest thing in the world to cut off the whole external part of a suture and leave its deeper part buried. It is frequently not realised that scissors which do not cut at their actual points are useless for this work; the point of the scissors cannot be inserted through the loop as in removing larger sutures.

In removing sutures from a newly-healed wound it is wise to begin by removing only alternate sutures. Only in this way can one be sure about the safety of removing the remainder. If the slightest separation of edges occurs it is wise to defer the removal of the remainder for another day or two. When all sutures must be removed particularly early, materials for preventing opening of the wound or stretching of the scar should be prepared beforehand. Half the wound may be protected in this way by the application of ribbon gauze or cotton wool soaked in collodion before the sutures are removed from the other half of the wound. The second half is then similarly protected. If sutures show signs of cutting into the skin surface they may be divided but not removed until some days later.

Two practical points which I have not seen mentioned elsewhere may be added before leaving this subject. The only part of suture removal which should produce any discomfort is the dragging out of the buried part of the stitch. In children especially it is a good thing to cut those sutures which are to be removed and to leave them for a moment. The patient, not having been hurt as he anticipated, gains confidence, and during the wait it will be found that the sutures have loosened themselves and can be picked out without pain. When

sedation has been used, again usually in children, it will be found that after the removal of several sutures the patient frequently becomes restless and resists further interference. The theory of the "summation of stimuli" in a more or less reflex animal probably explains this restlessness. A short pause gives a further period of peaceful suture removal.

CHAPTER II

Free Skin Grafts

The general surgeon should be prepared to cover any raw surface he produces; he should be prepared to carry out destructive operations, such as those for the eradication of malignant disease, unfettered by a fear of leaving disfigurement and confident that his operation can be planned in a manner calculated to avoid permanent deformity; he should be prepared to prevent those extreme contractures which so frequently come into the plastic surgeon's hands for correction; and he should be prepared to treat such conditions as ectropion before, and not after, loss of eyelid protection has resulted in corneal ulceration and opacity. For all these requirements he should know in more practical fashion than is usually the case how to make use of free skin grafts.

The parasitic quality of skin was demonstrated by Reverdin in 1869, though, centuries before this, reconstruction of the nose is said to have been carried out by means of free grafts from the skin of the buttock.

PINCH GRAFTS

Reverdin grafts are now seldom used, but their counterpart, the Pinch graft or small deep graft (Staige Davis)—epidermal at its margins and full-thickness in its centre—has a large field of usefulness in expediting epithelialisation in large granulating surfaces of the type produced by burns or by street accidents. The cosmetic result which such grafts give is usually poor and they leave disfiguring scars in the donor area. It is for this reason that they have found little favour in work about the face and neck.

Figure 2028 illustrates well the manner in which they are prepared and applied. A number of long straight cutting needles (Sim's abdominal) are employed. The donor area may be anæsthetised by local anæsthetic solution; the granulating surface seldom requires any anæsthetic, but it should be prepared beforehand by leaving off all antiseptic or greasy dressings for twenty-four hours before operation and applying simple saline gauze compresses. The grafts are cut by means of a No. 11 Bard Parker blade, the cone of skin being held up by

the point of the needle in the manner illustrated. A sawing or shaving action is employed in order to obtain a surrounding frill of epidermal graft. In order to avoid infection of the donor area the surgeon cuts the grafts and the assistant applies them, the needle returning from the recipient area being immersed in 1 in 20 carbolic acid solution and afterwards rinsed in saline before approaching the donor area again. These grafts should be roughly 0·5 cm. in diameter and should be firmly pressed down on the granulating surface, leaving intervals of about 0·5 cm. between them. Their epidermal frills should be carefully spread out by one needle while the other holds the graft in position. The grafted area is covered by some material which will not adhere but will allow free escape of secretions into the covering gauze dressing.

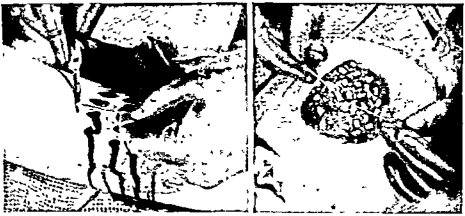

Fig 2028.—The cutting and application of Pinch or small deep skin grafts.

Tulle Gras, usually employed for this purpose, is an open mesh net material impregnated with vaseline containing 1 per cent balsam of Peru. It is prepared by Lumière of Paris and is supplied by the Anglo-French Drug Co. It has been found particularly suitable for dressing these areas. Previously, lint, spread or impregnated with vaseline, was employed but this provided a much too air-tight dressing, preventing the escape of serous or other discharge and converting the area covered by it into something of a hothouse in which organisms from the glandular elements of the surrounding skin appeared to thrive. Various modifications of the original material and instructions for its preparation for hospital use are described in an excellent paper by D. A. Beattie, published in the *Journal R.A.M.C.*, 1933, lx, 352.

The covering gauze is soaked in saline or in flavine and paraffin emulsion. The donor area is dressed in similar manner. It is a wise precaution to tack down the tulle gras over the grafts by a few marginal

sutures, picking up the surrounding skin to prevent shifting of the grafts during the application of the further dressings. When circumstances allow, it is a useful practice to paint the skin immediately surrounding the gauze dressing with mastisol and to apply an ordinary cotton bandage immediately. This helps materially in preventing any shift of dressings or grafts. Outside this, further absorbent material may be applied and snug pressure dressing provided by elastic adhesive strapping or crêpe bandage. The dressings are not disturbed for about five days unless constitutional symptoms or excessive discharge call for earlier interference. When grafting highly infected surfaces it is advisable to take down the dressing to the tulle gras layer earlier and to renew the outer gauze dressings after mopping away discharge. The majority of such grafts take completely and spread rapidly. Their appearance at the first dressing is characteristic: those which are living are pink and firmly adherent; those which have failed to take are grey or pearly white and will separate easily.

Drawbacks to this type of graft are: (1) Time taken in cutting and application; (2) Disfigurement produced in the donor area, for the scars tend to be keloidal; and (3) Poor cosmetic result in the grafted area.

Where large surfaces require grafting and where infection is not virulent, it is my practice to shave off granulations and apply sheets of Thiersch graft.

THE THIERSCH GRAFT

The credit for introduction of this type of graft is shared by Ollier and Thiersch, but it is convenient to call it by the name which has been attached to it for so many years. It was thought originally that it was composed only of epidermis, but it is impossible to cut a graft so thin that removal of deeper layers at some points is avoided.

When cut, a Thiersch graft should be uniform in thickness and should have the appearance of thin tissue-paper. It should leave a surface, with only tiny punctate hæmorrhages, on which epithelial growth is so rapid that healing is complete when the dressing is removed for the first time at the end of a week. It is in this respect that the Thiersch graft is so surgically economical; the donor area suffers little and may even be used again as the source of a graft at some later date, if necessary. The unpleasant keloid scars frequently encountered on patients' limbs, stated to be the sites from which Thiersch grafts have been taken, are evidence that many surgeons do not understand clearly what a Thiersch graft is, for it is obvious that the knife has penetrated deeply at some points or even throughout the graft. In the majority of

cases, Thiersch grafts are required to be hairless, and they are therefore usually taken from the inner aspect of the upper arm or the outer side of the thigh. The antero-internal aspect of the thigh is a difficult region from which to cut a good graft of uniform thickness and breadth, for it is impossible to place the limb in any position which does not leave an unpleasant and greatly-interfering muscular ridge. Unless it is immaterial whether the graft, in its transplanted position, does or does not grow hair, it is unwise to have the donor area shaved beforehand, for it then becomes difficult to decide what is and what is not hair-bearing skin. These remarks are made in spite of the fact that I am aware that, in theory at any rate, no Thiersch graft should carry with it hair follicles and, therefore, the capacity for growing hair. It is always well to be on the safe side and to avoid the necessity for removing, for example, those intra-oral beards which have more than once been seen following skin-grafting in the mouth.

Preliminary skin preparation should be carried out without pigmented antiseptics, and ordinary soap-and-water cleansing followed by methylated ether and then by alcohol has proved best for the purpose. At the time of actual operation a final wipe over with ether is all that is required; methylated spirit is inclined to make the knife slide less smoothly over the surface. When it is known beforehand roughly what area is to be grafted, it is as well to cut the graft first (and to cut it well over-size), in order to avoid the possible carrying of infection from the recipient to the donor area. Draping of the area should not be carried out in any slipshod fashion, for it should be considered "criminal" to infect the area from which the graft is cut.

At the risk of appearing to provide unnecessary detail, explicit instructions regarding preparation may be given, for there is no doubt that many a graft is doomed to failure from infection before it reaches its destination.

Experience has shown that there is only one completely satisfactory way of shutting off the arm area, and this is illustrated in figure 2029. The arm is held out from the body horizontally by a nurse for final skin preparation. A sterile towel is placed over the chest, level with the axilla and coming well down the side of the table. The upper arm is cleansed with ether as far as possible in this position. The arm is now raised to a vertical position, the already cleansed part coming into contact, if with anything, with the sterile towel and not with the blanket. The remaining surface of the limb is cleansed with ether, and two fresh towels, placed over the chest and face respectively, are clipped to the skin above and below, as in the illustration. A ring of mastisol is

painted around the elbow region, and a third towel is carefully draped over the hand and forearm with its upper edge fixed by the mastisol. A towel clip is inserted for greater safety. The nurse continues to hold the arm with the palm of the hand upwards during the cutting of the graft. She should not pull on the arm but should allow the elbow to be slightly flexed, while the upper arm rests on the knee of the surgeon whose foot is supported on a stool of convenient height.

Everything is now ready for the cutting of the graft. A sharp Thiersch knife or a newly-stropped razor, and a strip of wood with

Fig 2029.—Skin graft cutting by Blair knife preceded by wood slip. Arrangement of towels to shut off donor area.

smooth rounded edges, 8 inches by 3 inches and $\frac{1}{4}$-inch thick, are all that is required for the job. The under-surface of the knife or razor, and particularly its back edge, are smeared lightly with vaseline or liquid paraffin and one edge of the wood strip is similarly treated. Too liberal a supply of grease on the wood strip renders the skin surface of the graft unduly greasy and makes its later manipulation unnecessarily difficult.

SKIN GRAFT CUTTING APPARATUS

It is worth while diverging a little at this point to make some remarks on skin-grafting knives. There is little question that the best knife for the purpose is one of ample length prepared from wafer-steel of the pattern made by Tontrup of St. Louis, to the requirements of

Professor V. P. Blair. This knife has been copied in this country by Messrs. Down Bros. (fig. 2030) and is supplied with a very simple sheath which prevents damage to its edge when not in use. It is quite unnecessary and, indeed, disadvantageous to have such a knife ground and set after every operation. Blair himself employs a damp sterile towel smeared with sterile emery flour for stropping the instrument during the course of an operation, but the ordinary care which a man gives to his "cut-throat" razor for shaving purposes is all that is required to keep a graft-cutting knife in excellent condition for many months and for a very large number of operations. The knife should be carefully washed and dried after use and should be stropped immediately; it should also be stropped again immediately before use. It is best sterilised in lysol followed by alcohol, or in the latter alone. Expensive strops are supplied by most surgical instrument makers but none of these has been found one tithe so useful as a very low-priced three-sided strop, the Rosswaye Tri-side Strop, made and marketed by R. M. Ross, 26 Upton Road, Slough. The ordinary French razor made

$\frac{1}{4}$ Sc

Fig 2030.—The Blair skin-graft knife.

of soft steel, to which an excellent cutting edge can be given (even after considerable damage has been done to it) by a few strokes on such a strop, is eminently suitable for cutting smaller grafts, only its limited length precluding its use for larger ones. A special metal handle has been made for me for the French razor blades by Messrs. Thackray, which allows for the locking of the blade in the open position. The older, more expensive and heavier Thiersch graft knife can be kept in good condition in precisely similar manner, and at times one has felt that its weight and balance offer certain advantages.

The greased edge of the wood slip is applied transversely across the upper arm skin, just below the axilla, and its position is changed until a flat surface sufficiently broad for the required graft is produced. At one time a second wood slip was held above by an assistant, but this and all stretching or other manipulation of the skin were discarded many years ago, for these "helps" represent unknown factors and success depends upon a nice balance between the work of the two hands of the operator. In this procedure it is very essential that the right hand shall know precisely what the left hand is doing.

The knife now begins its work. It is applied to the skin surface

just proximal to the wood slip and is worked steadily to and fro with a gentle sawing movement until it begins to cut. Just as a saw should be allowed to cut its own way through wood, so no undue force should be employed to make the knife cut through the epithelial layers of the skin. It is difficult to explain exactly what is to be done with the wood slip. Sometimes it is necessary to stretch the skin by drawing it down the arm, sometimes to press the edge firmly against the skin, but usually one finds only the very lightest contact is required to render the surface sufficiently taut to allow of easy cutting. As the knife advances so the slip recedes before it, sliding easily over the skin by virtue of its greased edge. Practice on a piece of chamois leather stretched over a board is well worth while, for only practice can develop the proper touch.

Given a sharp knife, a modicum of skill and a reasonable amount of patience, graft-cutting should offer no serious difficulty. To this list of requirements, one should perhaps add a suitable patient, for there certainly are occasional individuals from whose skin it is extremely difficult to cut good grafts. In these it is probably undue thinness of skin which causes the difficulty, for when the skin is very thin and the tension produced by the wood is too great it is a very easy thing to cut through to fat, the skin splitting as though its contents were under tension and anxious to escape.

Mention must be made of various other forms of apparatus which have been devised to aid the skin graft cutter of limited experience. Although the simple knife and wood slip method may be easy to the man who is continually cutting grafts, it does not prove so easy to the occasional skin grafter. The essential point common to all is some means of providing a flat skin surface from which the graft may be cut. In 1921, in association with a colleague, T. Jackson, the writer described a simple skin-stretching device, illustrated in use in figure 2031. This, when made with sufficiently fine and sharp points on its cross-bars, does materially help in graft-cutting. It locks automatically and avoids that "bellying" of the underlying tissues which is often so troublesome. V. P. Blair employs a metal box attached to a suction apparatus and this, when suitably lubricated and drawn along the surface, draws up the skin in a flat line in front of the knife. Neither of these devices provides automatic knife action, and practice with the knife and patience are still required.

Lane-Joynt of Dublin, an expert craftsman in metals, designed an instrument which provides both flat surface and automatic cutting. The principle is that employed in leather splitting, the knife edge following a roller and being adjustable for wide variation in thickness of

graft. This instrument works perfectly so long as the knife is kept sharp and the moving parts are given reasonable care and attention. The sole objections to it are that its cost is high and that the need for insertion of subcutaneous plates makes of graft-cutting a major instead of a minor operation. G. Humby devised an instrument

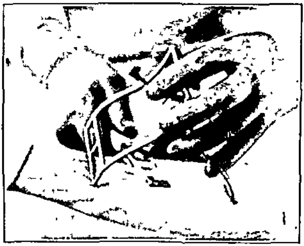

Fig. 2031.—Kilner's skin stretching apparatus in use.

working on somewhat similiar lines but in which the need for subcutaneous plates was avoided by the strapping of a frame to the limb. In this a removable and renewable wafer-steel blade was provided.

He has recently materially simplified his knife, and the latest model, which provides a most efficient means of cutting grafts of varying thickness, is illustrated in figure 2032.

Any instrument which will provide a ready and certain means of graft-cutting must prove a boon to surgeons and patients alike, but as

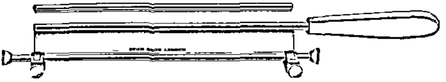

Fig. 2032.—Humby's skin-graft knife.

few surgeons have time and patience to adjust and care for mechanical devices the writer maintains that the simpler the apparatus the more rapidly may the technique be mastered, and the more frequently will the general surgeon be persuaded to employ it in his work.

The graft obtained, it is laid flat on a sheet of gauze moistened with warm saline and is covered by another similar piece of gauze and placed on the table, suitably guarded by a red towel or other means lest it should be lost before it is required. This precaution is necessary,

for, though it barely seems possible, grafts have been seen reaching the main operation area long before they were really required, dragged there unwittingly in swabs or adhering to the sleeve of an assistant or nurse.

The area from which the graft has been cut is now wiped dry and covered with a layer of tulle gras, over which are placed several layers of gauze wrung out of saline. After the application of this dressing, the arm is entirely discarded by the surgeon and handed over to a nurse for bandaging. The precautions already mentioned against shifting of dressings are employed, for otherwise the donor area may easily cause more discomfort than the area grafted.

The recipient area for the graft is now dealt with as an entirely separate procedure. Only in this way is it possible to maintain any degree of asepsis throughout such a two-stage operation. There are, of course, exceptions to this rule, when, for instance, a graft is cut from one part of an arm or leg for transfer to some other part of the same limb. In these cases the whole limb can be prepared at once and there is no need to divide the operation into two such definitely separate procedures.

Whenever the raw surface to be covered possesses *cavity* form, it is advisable to make an accurate mould of it in dental modelling composition (Stent). Such a mould greatly facilitates the application of the graft and ensures contact of the graft at all points on even the most irregular surface. The tablets of Stent are best prepared for use by standing in 1 in 20 carbolic solution until required. This sterilises their outer surfaces which have been subjected to handling. They may, alternatively, be kept sterilised in a jar containing formalin vapour, and are then handled by forceps. When required, they are immersed in boiling water, and when soft are worked up into a smooth mass which is applied to the raw surface and pressed home to fill the whole defect. It has been found of advantage to stretch over the mould a piece of gauze held in such a manner as to imitate the pressure which will be produced by the final dressing. While so held in position the Stent is hardened by dripping over it a stream of iced saline, either from a swab or, more effectively, from a dental chip syringe. When set, the mould is removed and dried. Careful note is made of the impression area and over this the graft is uniformly spread, raw surface outwards. When the surface to be covered is very large, several grafts may be required. These should be so arranged that their edges overlap slightly.

The raw surface is cleared of blood clots and the graft-covered mould is applied. The skin surrounding the defect is wiped with ether

and is smeared with mastisol, as is also the exposed surface of the mould. The margins of the graft or grafts are turned over on to the surrounding skin edges, and the mould is provided with initial fixation by the application of ribbon gauze strips held by the mastisol. The whole area is covered by layers of gauze or wool, and firm pressure is maintained by either a crêpe bandage or elastoplast strapping.

Figure 2033 illustrates the result to be expected from grafts applied on moulds in this manner to the interdigital clefts, while figure 2034

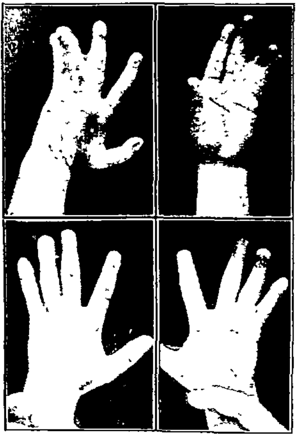

Fig 2033.—A case of congenital syndactyly treated by division of the webs and Thiersch grafting of raw surfaces on Stent moulds.

illustrates the result of grafting the slightly depressed area produced by the excision of fibrosed skin and fascia in a case of Dupuytren's contracture. An area commonly treated in similar fashion is the large depressed raw surface left by excision of an X-ray burn of the back.

I no longer use the Stent mould when the raw area is on a flat surface for I feel that in such situations the mould is liable to shift its position and drag the graft from its bed. Figure 2035 indicates the technique employed in such areas. The graft is spread on the raw

surface, bleeding having been arrested as far as possible by pressure and the application of iced saline, and is marginally sutured by mattress stitches of fine silkworm-gut passed on an eyeless needle. When several grafts are required, their edges are slightly overlapped and may be fixed by occasional mattress stitches passing through the two layers of graft and picking up the raw surface below. The graft is covered by a layer of tulle gras and any underlying blood is expressed by rolling

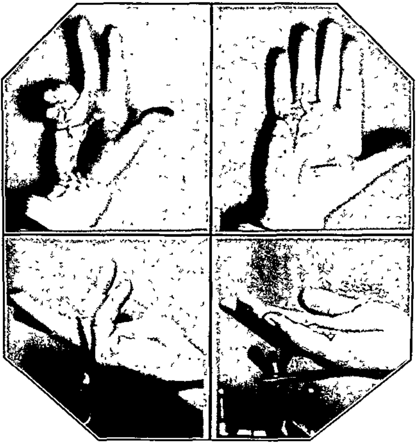

Fig 2034.—A CASE OF DUPUYTREN'S CONTRACTURE TREATED BY FREE EXCISION OF FIBROSED FASCIA AND SKIN. A THIERSCH GRAFT WAS EMPLOYED TO COVER THE RAW SURFACE WHICH REMAINED.

over the area a folded gauze swab. A pressure dressing of cotton wool soaked in saline or flavine and paraffin emulsion is then built up over the graft and the whole dressing is firmly fixed by the means already fully detailed. Careful splinting of a limb so treated must not be overlooked. When the surface to be grafted is a granulating one, it is advisable, as has been mentioned previously, to shave off the granulations with a sharp scalpel or graft knife. This removes a layer of tissue which is likely to be infected and which, in any case, produces discharge capable of preventing correct apposition of the graft. It leaves

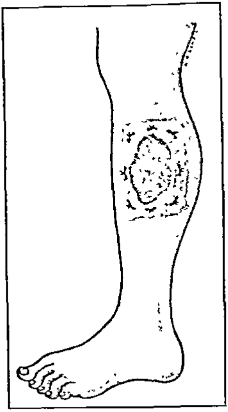

Fig. 2035.—Method of application of a Thiersch graft to a surface defect. Marginal fixation by fine mattress sutures.

a surface with punctate hæmorrhages very like that left in the donor area. Figures 2036 and 2037 illustrate cases treated in this manner.

In the neck region a similar method is employed, though here it is sometimes advisable to use a Stent mould of ample proportions which

Fig. 2036.—Extensive granulating surfaces following severe burn of buttocks and thighs treated by application of large Thiersch grafts. Two small areas where small deep grafts were used are also shown.

will act in the dual capacity of pressure dressing and splint to restrict movement of the parts. Figure 2038 illustrates a result obtained in this manner.

Plaster-of-Paris fixation has a definite place in all plastic work, but it has to be remembered that it is difficult to prepare plaster-casts

Fig 2037.—Long-standing granulating surface following extensive burn treated in several stages by the application of Thiersch grafts. The granulations were removed by shaving before the grafts were applied.

Fig 2038.—*X-ray burn of neck* treated by excision and the immediate application of a Thiersch graft on a Stent mould. It will be noted that the initial depression of the grafted area has entirely disappeared.

beforehand for cases in which contractures are present, and their preparation at the time of operation adds a further long period to what has probably already been a rather prolonged operative procedure.

Post-Operative Care

The donor area is left entirely untouched for at least a week, and

it is usual at that time to be able to peel off the dressing readily and painlessly and to find a completely epithelialised surface already present. The grafted area is also left undisturbed for seven to ten days unless rise of temperature, pain or excessive discharge indicates the need for earlier dressing. The outer dressings are removed down to the mould. The edges of this, which have become glued by inspissated serum and blood, are moistened with peroxide of hydrogen until the mould can be loosened and removed without dragging the newly adherent graft with it. Redundant edges are trimmed away and the surface of the graft is gently dabbed clean of secretions. Any blisters which have formed owing to collections of blood or serum under the graft are opened and evacuated.

Pressure is maintained by a bandage over cotton wool or gauze soaked in flavine and paraffin emulsion. The dressing is changed every two or three days, and a fortnight after operation the grafted area should be ready for gentle grease massage. Liquid paraffin, lanoline cream or cocoa butter may be employed for this purpose. Drying up of the graft should be prevented by keeping its surface slightly greasy. The after-treatment where no mould has been employed is precisely similar, but frequently there is no need to disturb the layer of tulle gras at the first dressing.

The Application of the Thiersch Graft to Special Areas

Thiersch-graft skin is particularly suitable for replacing lost mucous membrane, since mucous membrane itself is difficult to procure in anything like quantity and is, for the most part, placed in rather inaccessible positions. The use of the epidermal graft for this purpose in the eye socket and in the mouth will be taken as examples, and its use on the eyelid will also be described.

Orbital Graft.

The distorted eye socket is prepared by careful excision of all mucous membrane from the inner aspect of the eyelids and from the back wall of the socket. It is better to make a completely skin-lined cavity than to leave mucous membrane remnants producing discharge and spoiling the appearance of an artificial eye. For the removal to be performed efficiently, suction apparatus is almost imperative, for bleeding is usually troublesome and no other means will keep the mucosal surfaces clearly under observation while they are being separated and cut away with scissors. Both upper and lower fornices are deepened, to an extent beyond the normal, by incision and by the removal of any scar tissue encountered in these regions. Hæmostasis

is obtained by picking up and twisting any bleeding vessels, and by means of ice-cold compresses.

Care should be taken in using the suction apparatus lest undue traction is made on orbital fat, for it is desirable that this should be disturbed as little as possible and that a smooth surface should be left to receive the graft.

A Stent mould is made of the over-large cavity thus produced, the eyelids being drawn gently together over it, either by traction sutures or by fine tissue hooks, during the setting process, which is hastened by a trickle of iced saline from a dental chip syringe. Careful attention should be given to filling out the fornices, and the Stent should be moulded into disc-shaped form. Instead of the Stent mould I frequently employ in this situation hollow glass shapes made by Millauro.

It is not altogether essential, but because disappointments have resulted from the too early extrusion of the mould in the after-treatment of these cases, the edges of the eyelids are usually freshened in their middle thirds at this stage in readiness for approximation by suture later.

It is a wise precaution to mark the mould in some convenient manner (as by scratching with a needle) to indicate its front surface and one or other of its extremities, for these moulds are almost symmetrical in shape, and these points are not always easy to recall when the mould has been removed and the graft applied. When set, the mould is removed and dried, and is then draped with the Thiersch graft, raw surface outwards, the junction line of graft edges being arranged to lie in front in line with the palpebral fissure. If the graft is really an epidermal one and is amply large for the job, no difficulty will be experienced in spreading it over the mould. If it is thick and more nearly approaching the Wolfe graft in character (and, therefore, unsuitable for use in this region because it will almost certainly grow hairs), its edges will continually curl back and give endless trouble in spreading. The graft-covered mould is inserted and the freshened portions of the eyelid margins are approximated by a running subcuticular suture. A mild pressure-dressing of gauze or wool is applied over a piece of tulle gras and is retained in position by a crêpe bandage.

Unless pain or tenderness to pressure over the dressing is experienced, the area is left undisturbed for a week, after which any discharge is gently mopped away and the eyelid suture is removed. Gentle irrigation or mopping of the open parts of the palpebral fissure is carried out daily, and the region is kept covered by a pad and bandage or an eye-

shade. The longer the mould can be retained, the more certain is it that a perfectly epithelialised cavity will be found when it is removed. It is for this reason that a glass shape is frequently employed in preference to a Stent mould, since the surface of the latter is liable to become macerated after a time and appears to produce a certain degree of irritation.

The patient leaves hospital soon after the first dressing, and continues to carry out the simple post-operative toilet himself, returning periodically for inspection. Occasionally, inflammatory reaction is encountered, due to retention of discharge behind the mould, or to neglect to keep the open parts of the palpebral fissure draining freely. This complication is not serious and is readily dealt with by free irrigation.

In four to six weeks, when all danger of contraction in the grafted area is past (and this region above all others is especially prone to contraction), the bond of union between the eyelids is divided by a single cut with fine scissors. No anæsthetic, or at most only the injection of a few drops of local anæsthetic solution, is required for this. The mould is removed, and the socket is mopped clear of the epithelial debris arising from original excess of graft, or from desquamated surface layers.

Fig. 2939.—Restoration of eye socket, capable of accommodating artificial eye, by Thiersch graft applied on Stent mould.

At this stage a normally shaped artificial eye of larger-than-normal size is fitted. If such a prosthesis is not immediately available, the mould is replaced and the patient carries out a daily toilet of the socket until he can visit the artificial eye maker. Eyes of gradually decreasing

size are fitted, and finally one of correct shape, size and colour is prepared. It seldom happens that a socket is made too large; very frequently insufficient allowance is made for subsequent contraction. Figure 2039 illustrates a case treated in the manner described.

Symblepharon.

A further modification of this method of grafting has been found useful in cases of symblepharon. It is used as a preliminary measure to corneal grafting or to the fitting of a shell prosthesis in cases where the cornea has been rendered opaque and disfiguring. For this purpose sheet wax, known to dentists as "pink wax," has been found the most suitable material on which to apply the graft.

After freeing of the eyelids from the globe by careful dissection and the removal of scar tissue, a flat disc of this wax is cut, of such proportions that it will fit snugly over the eye and well upwards and downwards into the fornices. This mould is rendered pliable by leaving it for a few seconds in warm water. It is hardened when in position by a stream of cold water delivered by a syringe. In order to avoid undesirable pressure on the cornea, or to relieve it entirely of such pressure in cases where it is undamaged, a suitable circular piece is cut from the mould. The Thiersch graft, already taken, is draped over the mould from behind forwards, covering completely the posterior (ocular) surface and having its edges meeting on the anterior (palpebral) surface along the line occupied by the palpebral fissure. The draped mould is inserted, and the circular area of graft exposed in the central opening is removed so that the cornea is exposed.

The eyelids are now approximated in their central thirds in the manner already described, and a similar dressing is applied. The eye should be examined daily and a careful watch kept for untoward signs or symptoms. After the first few days gentle irrigation may be used to wash away unwanted redundant graft or epithelial debris. The mould should be retained for some 2–3 weeks if practicable. It can readily be removed without separating the lid adhesion, for the wax can be divided by scissors into two pieces which are easily extracted laterally. The eyelids are usually separated, however, at this stage, and free movements of eye and eyelids are encouraged.

Further stages in the treatment of such cases are described in a paper published in the *Trans. Ophth. Soc.*, XLIV, 1929, by Gillies and Kilner.

Ectropion.

Whilst dealing with the orbital region, a brief description may be given of the treatment of cicatricial ectropion. The details of the

size are fitted, and finally one of correct shape, size and colour is prepared. It seldom happens that a socket is made too large; very frequently insufficient allowance is made for subsequent contraction. Figure 2039 illustrates a case treated in the manner described.

Further stages in the treatment of such cases are described in a paper published in the *Trans. Ophth. Soc.*, XLIV, 1929, by Gillies and Kilner.

Ectropion.

Whilst dealing with the orbital region, a brief description may be given of the treatment of cicatricial ectropion. The details of the

technique employed are well illustrated in figure 2040. The principle involved is that *already stressed as essential in all free skin-grafting, namely*, accurate pressure dressing giving complete apposition between graft and bed. In the eyelid region this desideratum is obtained by stretching the eyelid outwards over the graft-covered mould by means of sutures. The writer is convinced that this, the original method of applying the graft developed by Gillies at the Sidcup Hospital, is superior to any other. for only by this means can efficient over-correction be obtained,

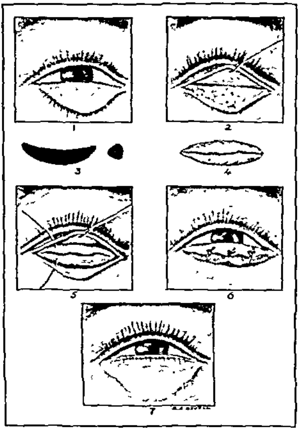

Fig 2040.—Treatment of ectropion by a Thiersch graft applied on a Stent mould.

and allowance thus be made for some degree of subsequent contraction. For a time the newly-grafted surface remains depressed, but this hollowness quickly disappears on light grease massage. Figure 2041 illustrates a case treated by this method.

Early grafting of ectropic eyelids in burn cases is to be most strongly advocated if corneal ulceration and opacity are to be avoided. Further contraction may occur in such cases and ectropion may reappear, but the operation is simple and can readily be repeated.

Intra-buccal Grafting.

In the mouth the Thiersch graft is chiefly useful for the reconstruc-

tion of an obliterated sulcus. In post-War surgery such deformity was extremely common after gunshot fractures of the mandible or maxilla. In civil practice the "buccal inlay," as it has been termed, finds its chief fields of application in restoring contour in the chin region, in the

Fig 2041 —A CASE OF GROSS FACIAL DISFIGUREMENT FOLLOWING ACID BURN. ECTROPION TREATED BY THIERSCH GRAFTS APPLIED ON MOULDS.

premaxillary region in cleft lip and palate deformity, or in the treatment, by the Gillies method, of the "dish-face" deformity so frequently associated with luetic infection.

It is likely to be used increasingly for the re-formation of a buccal sulcus in edentulous cases with excessive absorption of the alveolar bone in which the fitting of a stable denture is otherwise impossible. An example of the use of this method in a case of extreme retrognathism

following trismus is illustrated in figure 2042, while figure 2043 illustrates a case of severe cleft lip and palate deformity treated in a similar manner. In these cases the final contour depends on the shape and size of the dental prosthesis fitted in the skin-lined pocket provided for

its reception. In the luetic nose the original mould is later dispensed with in part or altogether. for the final support of the nose bridge is provided by a hinged cartilage graft from the patient's 7th or 8th costal cartilage. A case treated in this manner is illustrated in figure 2044.

For work of this kind in the mouth, dental apparatus is employed in the form of a metal-cap splint carrying an adjustable flange to press

other applications. Figure 2045 makes this method amply clear when considered with its full legend.

Intra-buccal skin-grafting can be employed with advantage in many general surgical conditions where raw surfaces, leading to disfiguring contraction, are commonly left to close by granulation. An example of such a case is given in figure 2046, where the left maxilla has been

Fig. 2045.—A development of the Ivy loop method of inter dental wiring for the retention of moulds for intra buccal and nasal skin-grafting.

removed for growth. Had a simple half denture been prepared beforehand in this case, provided with clip fixation to the teeth on the right side, and with a projection to the left to support a Stent mould, the whole of the raw surface left by removal of the maxilla could have been readily epithelialised and all disfigurement prevented. Modification of the denture later would have built out the cheek in perfect form, and the necessity for the further operation required would have been avoided.

In the absence of dental apparatus or when teeth are not available

for the alternative method of fixation described above, moulds may be held in place, long enough to ensure satisfactory grafting, by suitably placed silkworm-gut sutures.

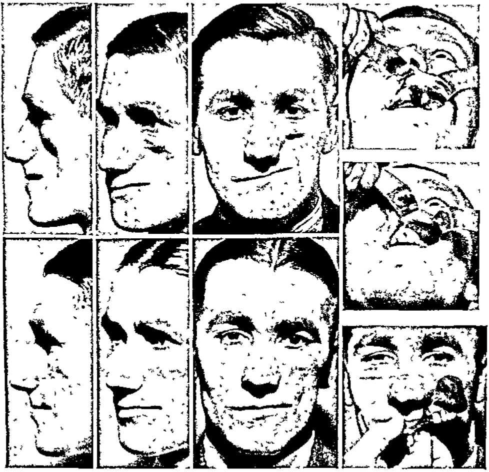

Fig 2046.—A case in which the left maxilla had been removed for growth and the cheek tissues had been allowed to contract The deformity was corrected by the preparation of a Thiersch grafted pocket accommodating an extension from the upper denture

THE WOLFE GRAFT

Although several previous attempts had been made to transplant whole-thickness skin, with varying degrees of success, the credit for the introduction of this form of free skin graft is usually given to Wolfe of Glasgow who, in 1875, described his successful use of the material in the reconstruction of a lower eyelid. In 1896, Krause reported the use of the same type of graft in a large series of cases and described in great detail a technique which differs little from that employed to-day. In view of this work, in which full credit was given to the earlier reports of Wolfe and others, it is not unreasonable that this graft should be named, as it frequently is, the Wolfe-Krause graft. " Full-thickness,"

other applications. Figure 2045 makes this method amply clear when considered with its full legend.

Intra-buccal skin-grafting can be employed with advantage in many general surgical conditions where raw surfaces, leading to disfiguring contraction, are commonly left to close by granulation. An example of such a case is given in figure 2046, where the left maxilla has been

removed for growth. Had a simple half denture been prepared beforehand in this case, provided with clip fixation to the teeth on the right side, and with a projection to the left to support a Stent mould, the whole of the raw surface left by removal of the maxilla could have been readily epithelialised and all disfigurement prevented. Modification of the denture later would have built out the cheek in perfect form, and the necessity for the further operation required would have been avoided.

In the absence of dental apparatus or when teeth are not available

for the alternative method of fixation described above, moulds may be held in place, long enough to ensure satisfactory grafting, by suitably placed silkworm-gut sutures.

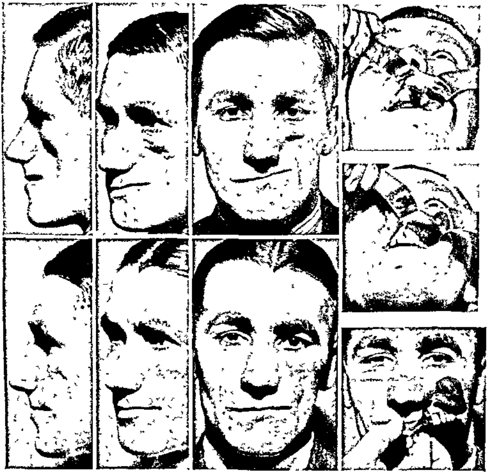

Fig 2046.—A CASE IN WHICH THE LEFT MAXILLA HAD BEEN REMOVED FOR GROWTH AND THE CHEEK TISSUES HAD BEEN ALLOWED TO CONTRACT. THE DEFORMITY WAS CORRECTED BY THE PREPARATION OF A THIERSCH GRAFTED POCKET ACCOMMODATING AN EXTENSION FROM THE UPPER DENTURE.

THE WOLFE GRAFT

Although several previous attempts had been made to transplant whole-thickness skin, with varying degrees of success, the credit for the introduction of this form of free skin graft is usually given to Wolfe of Glasgow who, in 1875, described his successful use of the material in the reconstruction of a lower eyelid. In 1896, Krause reported the use of the same type of graft in a large series of cases and described in great detail a technique which differs little from that employed to-day. In view of this work, in which full credit was given to the earlier reports of Wolfe and others, it is not unreasonable that this graft should be named, as it frequently is, the Wolfe-Krause graft. " Full-thickness,"

"dermo-epidermal" and "dissected" are alternative names for the same material.

The Wolfe graft consists of the full thickness of the skin down to, but not including, subcutaneous fat. It is outlined by a sharp scalpel and freed in much the same manner as that employed in raising skin in the dissecting room. When the outlining incision is being made the skin should not be stretched; once this incision is completed, stretching of the skin by an assistant facilitates the removal of the graft. The graft should be cut to precisely the size and shape of the defect it is to fill and no allowance be made for contraction as was at one time advised. It is essential that lymph spaces should be kept open in as nearly as possible normal state if early establishment of nutrition is to be assured. In order to ensure this, a pattern is made in tinfoil, cellophane, or other convenient material, of the area to be covered, and this, applied to the donor area, is used as a guide for the outlining incisions. With very few exceptions it is impracticable to cut a Wolfe graft (as it is possible and desirable to cut a Thiersch graft) before dealing with the recipient area.

The ulcer or scar is carefully and freely excised, when possible well out into normal surrounding skin and down to healthy subcutaneous tissue. Undermining of the edges is to be avoided for this may lead to hæmatoma formation. The margins of such a wound usually retract spontaneously and sometimes to a surprising extent once they are freed from the scar tissue. It is only after this has occurred that it is possible to judge the size of the graft required, and it is for this reason that the taking of the graft is deferred until this stage. Hæmostasis is of paramount importance and is obtained, without ligatures, by the firm application of gauze sponges wrung out of iced saline solution or by blowing a stream of air on the surface from a hair-drying machine. Where discrete bleeding vessels persist, diathermy coagulation may be employed, but the areas of coagulation should be kept as small as possible.

The pattern is now cut and is marked in any convenient manner to indicate its outer surface and, if of roughly symmetrical shape, at least one of its extremities. It is surprisingly easy to find oneself with a perfectly cut graft which will fill the defect only with its raw surface outwards if these precautions are not taken, and if the pattern is not transferred immediately to the donor area.

In order to maintain strict asepsis in the donor area and more especially when some infection is present in the recipient area, the pattern may be boiled or otherwise sterilised at this stage and the operator's gloves may be changed or washed.

The graft is now cut in the manner described, avoiding all unnecessary trauma by the use of fine tissue hooks in lieu of dissecting forceps. I found the earlier form of tissue hook (Gillies) too thick and large for this purpose and this led me to design the particularly fine hook with detachable handle already illustrated (see fig. 2026). By this means the possession of really sharp hooks can be assured at all times, for the hook portion of the instrument may be discarded for replacement or repair whenever it becomes blunt or otherwise damaged. The graft is spread out on the pattern, correctly orientated and, wrapped in gauze soaked in warm saline, is put on one side while the raw surface left by its removal receives attention. If the raw surface is a small one it may be closed by direct approximation of its edges, after suitable undermining, but this procedure frequently leads to the formation of a keloidal scar. If left to epithelialise spontaneously, healing is delayed for several weeks, the wound is a painful one for dressings, and the resulting scar is often a very disfiguring one. For some time now it has been my practice to cut a Thiersch graft from the neighbouring skin and to apply it with marginal suture fixation and pressure dressing to the raw surface. This ensures a perfectly healed surface in 7–10 days.

The graft is transferred to the recipient area and placed in correct position by reference to the markings on the pattern. Single sutures are placed at four cardinal points, and the edges of the graft are then very carefully stitched to the margins of the defect by a fine silkworm-gut suture on an eyeless (atraumatic) needle applied in continuous end-on (vertical) mattress fashion. The edges are handled very gently with fine dissecting forceps or with the fine tissue hooks already mentioned. All blood is expressed from under the graft, by rolling a folded gauze sponge over it, before the final points of the suture are inserted. A layer of tulle gras is applied and a pressure dressing is built up of cotton wool soaked in either saline or flavine-paraffin emulsion. This dressing is held snugly in position under gentle elastic tension by the application of elastoplast strapping or a crêpe bandage. Ferris-Smith, doing experimental work on such grafts, found that the ideal pressure was 30 mm. mercury, and provided this by incorporating in the dressing a rubber bag (fig. 2047), which could be kept pumped up to this pressure by means of a sphygmomanometer apparatus. Sorbo rubber and sea sponges have been used for the same purpose. In the majority of situations the technique described is sufficient; in others, where application of pressure to an irregular surface is required, the pressure-bag method repays the extra trouble it entails.

Coelst of Brussels has recently described (*Revue de Chirurgie Structive,*

Dec. 1935, 105) *an ingenious method of fixing the grafted area by* means of a " frame " cut in celluloid and attached by fine sutures to the surrounding skin. Over the graft itself he applies either a Stent mould or a sheet of celluloid held in position by a number of sutures passed from side to side of the surrounding frame. When a celluloid covering is employed it is possible to observe the progress of the graft without disturbing the fixation. Coelst stresses the importance of fixation (*contention*) rather than of pressure.

Perforations or snicks in the graft may be employed to provide for escape of blood or serum, but these detract from the cosmetic result

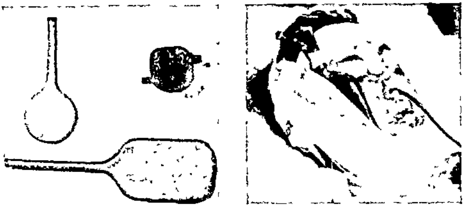

Fig 2047.—Ferris-Smith pressure bags employed to maintain uniform pressure on full-thickness (Wolfe) skin grafts.

and are not necessary when hæmostasis and uniform pressure-dressing can be obtained.

Wolfe *grafts are most successful when the recipient area is backed up* by bone; they are least likely to succeed on soft mobile surfaces. When a limb is under treatment, splinting of adjacent joints should be provided.

It has been shown by Staige Davis and Traut that the Wolfe graft derives its early nutrition from lymph exuding from the raw surface under it. It is for this reason that it is so important that all receptive lymph spaces shall be normally open and not closed as they would be *were the graft cut larger than the defect. Vessels grow in rapidly from* the edges of the defect, and actual bleeding from such a graft has been noted in eighty-four hours. The dressings are left undisturbed for about seven days, when the surface of the graft and the suture line are very gently wiped and the sutures are removed. The dressing is reapplied and pressure is maintained for a further 5–7 days. Bullæ sometimes develop, which should be snipped with fine scissors and treated with a 1 per cent watery picric acid solution. Any small area of

surface necrosis should be treated in similar manner, the object being to maintain a state of dry and localised, rather than of moist and spreading, gangrene. Massage, preferably with some greasy preparation such as cold cream, lanoline cream, or cocoa butter, will do much to keep the graft soft and supple. Without it, the surface epithelium becomes dry and dirty-looking and takes a considerable time to shed itself. Occasionally the whole of a Wolfe graft may be lost owing to the formation of a hæmatoma under it, while frequently small areas of necrosis occur which may rob the result of cosmetic perfection. The marginal scar is usually good, but in some cases it is keloidal and requires suitable radium

Fig 2048.—A pigmented hairy mole treated by excision and immediate application of a Wolfe graft

treatment. While contraction in a Thiersch grafted area is by no means uncommon, little or no contraction occurs in an area successfully grafted with whole-thickness skin. In some individuals a Wolfe graft remains dead white and may stand out as a very obvious patch ; in others, apparently as the result of blood disintegration in its substance, it may take on a peculiar dirty brown tinge which may last for a long time or even be permanent. Expression of blood from the graft before sewing it in position may prevent this discolouration.

It is important to choose, for an exposed, normally hairless region, a donor area free from hairs, and for this reason shaving should play

Fig. 2049.—Extensive scarring of left cheek following lupus treated by excision and Wolfe grafting.

no part in pre-operative preparation. Even when this point has received careful attention trouble may be experienced from the free growth of hairs which were absent or barely visible in the donor area.

Figures 2048–2052 show results of various types of case treated with the Wolfe graft.

Hairy Wolfe Graft.

Free full-thickness grafts may be taken from the scalp or other hair-bearing regions. Such grafts will survive and continue to grow hair, and are of particular value in the restoration of eyebrows in cases

Fig. 2050.—A pigmented hairy mole treated by excision and the immediate application of a Wolfe graft.

Fig 2051.—Defect in lip produced by dog bite treated by immediate application of a Wolfe graft.

of severe facial burns. The technique employed differs in no essential detail from that already described but, where practicable, due attention should be given, both in taking and in planting the graft, to the direction of the hairs. Although ideal in theory, I have had little success with the transplantation of hairy skin from the pubic region to fill defects in the hairy scalp.

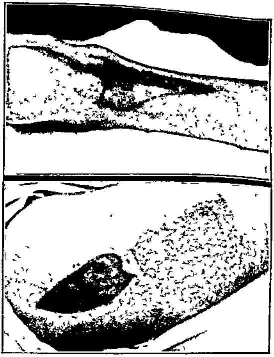

Fig. 2052.—Wolfe graft employed to cover raw surface produced by excision of a chronic ulcer. The lower photograph shows the donor area treated by the application of a Thiersch graft taken from the neighbouring skin area.

THE INTERMEDIATE, SPLIT-SKIN OR THICK RAZOR GRAFT

This graft, used extensively by Blair and Brown, usually cut by the help of the suction box already mentioned, takes a place midway between the Thiersch and Wolfe grafts both as regards certainty of

Fig 2053 —A GRAFT OF INTERMEDIATE THICKNESS (SPLIT-SKIN) USED TO REPLACE THE DISFIGURING SCAR OF CHEEK AND LIP RESULTING FROM TREATMENT BY VARIOUS MEANS OF A CAPILLARY NÆVUS.

" take " and final appearance. Either the Lane-Joynt or the Humby apparatus may be employed for cutting such grafts. Figure 2053 illustrates the result of such a graft on the cheek and upper lip.

SIEVE GRAFT

Douglas has described this graft—a full-thickness graft with numerous circular perforations corresponding to islets of skin left behind on the donor surface. With this, again, the cosmetic result is likely to be far from ideal, while the method of Thiersch grafting the raw surface in the donor area does away with the necessity for assisting healing by leaving behind islands of skin.

BURIED GRAFTS

Braun has revived a method of burying thin Pinch grafts, originally described by Pollock in 1870. McLennan and Keller have separately described *Tunnel* grafting—the introduction of full-thickness skin strips into tunnels made below a granulating surface. Thiersch graft strips have been woven into similar surfaces while epithelial paste, obtained by scraping moist skin with a knife, has been injected below such granulations. The probable explanation of any success with these latter methods is the " natural " pressure dressing and accurate apposi-

tion of graft to bed which the procedures provide. All have their uses in selected cases.

Mention should be made at this point of the results of attempts to graft from one individual to another of the same species (homo-skin-grafting) and from a member of one species to a member of a different species (hetero-skin-grafting).

The evidence is very conflicting but for all practical purposes the dictum of G. C. Padgett given in an Editorial on the subject in *Surgery, Gynecology and Obstetrics* (Dec. 1932) may be accepted as correct: " Isodermic (homo-) skin-grafting is not practicable except possibly from identical twin to identical twin."

In many cases where homo- or hetero-skin-grafting has been attempted, immediate " take " of the graft has been satisfactory but the whole graft has " dissolved " in the course of a few days to a few weeks. Near relationship appears to be of more importance in this connection than blood-grouping.

The use of homo-skin-grafts may be indicated, even although no permanent epithelialisation may be obtained by this means, in small children denuded of large areas of skin by burns, scalds, or other forms of trauma.

On three occasions when Gillies has attempted to transfer a skin flap carrying its own blood supply from one individual to another, complete failure of " take " has resulted. These cases were reported in the Charles H. Mayo Lecture published in *North-Western University Bulletin*, Vol. XXXV, No. 20, Jan. 1935.

CHAPTER III

Other Forms of Free Graft

A. FAT GRAFTS

Free grafts of fat are particularly useful in building up contour where a rounded soft outline is desired. Fat for this purpose may be obtained in ample quantity from the abdominal wall of the average individual; alternatively it may be taken from the thigh. It should be remembered that fat, having a low intrinsic "vitality," is particularly prone to infection, and careful aseptic precautions should, therefore, be exercised in both donor and recipient areas.

An incision is made through skin only. On the abdominal wall it is as well to place this incision away from the region where classical incisions for intra-abdominal operations are made, lest confusion arise later in the patient's history. The edges of the wound are held up by fine tissue hooks and the skin is undermined on a superficial plane sufficiently widely to expose the desired amount of fat. Fat grafts gradually shrink to about two-thirds the volume they possess at the time of insertion, and this must be remembered when the graft is being cut. The wound edges are widely retracted and the graft outlined by a scalpel. The area of fat thus separated is freed from its deep connection by scissors and the graft is placed on one side, wrapped in gauze wrung out of warm saline. All bleeding vessels are picked up and ligatured. Bleeding is usually free and there is danger of hæmatoma formation in the dead space left by the removal of the graft. It is wise, therefore, to insert a small drain in the suture line. An attempt is made to obliterate the space by end-on mattress sutures passed through the skin and picking up the fat surrounding the space. Occasionally these are made to pick up the deep fascia also. The area is temporarily covered by gauze, and at the end of the operation a pressure dressing is built up over this and held in position by elastic adhesive strapping.

Conditions in which fat grafts are found useful are the depressed scar areas sometimes following radical operation on the frontal sinuses, depressed malar and cheek areas where bony replacement has not been carried out early in treatment or where there has been bone loss, and

depressed scars following cervical adenitis where local fat flaps are not available or provide insufficient bulk to fill the defect. They are seldom useful in nose work, for here greater definition and support than they will supply is required. They are occasionally inserted at a later date under the Thiersch graft employed for the correction of ectropion. Theoretically they should be useful in the pectoral region for reconstructing contour, for example, after the removal of the breast. I have never yet had a case where such reconstruction has appeared justifiable, the danger of stirring up further disease having weighed heavily against purely cosmetic considerations, which can readily be met by simple prosthetic means.

The skin of the area to be raised is carefully undermined, access being obtained either by excision of an existing scar or by a fresh incision placed in some inconspicuous position. Bleeding is again usually free and is difficult to control except by pressure or packing, since undermining is of the blind variety and bleeding points cannot be exposed. The fat is cut roughly to the shape of the recipient cavity and is merely packed in, or may be guided into position by sutures passed through the skin at the extremities of the cavity and through the corresponding angles of the graft. These sutures are of the mattress variety and are loosely tied over small gauze rolls. A few points of suture are passed between the margins of the wound, and these, held up by an assistant, bring the skin edges together for the insertion of interrupted skin approximation sutures. The wound edges should be accurately apposed and great care should be taken that no particles of fat separate them. The wound is dressed and the whole area provided with a dressing supplying gentle and uniform pressure. A careful watch for infection or hæmatoma formation should be kept. In evacuating blood or serum, care must be taken that the graft itself is not extruded also. Occasionally a fine drain of twisted silkworm-gut is indicated, but it should be remembered that while providing egress for blood this increases the liability to ingress of infection from the skin surface.

It has been suggested that such grafts do not persist as fat but become organised into fibrous tissue. I have had reason to explore areas where fat grafts have been inserted many years previously and I have encountered fat which to the naked eye differs in no way from normal fat.

The need for over-correction has already been mentioned. It will bear re-stressing: It is a very easy thing to excise a little fat if the over-correction persists when the parts have settled down; it is

troublesome to have to go through the whole process of taking and inserting another fat graft.

The final photograph of the case illustrated in figure 2054 indicates how effectively a free fat graft may be employed to restore the soft contour of the cheek.

When sufficient local material is present, the correction of a depressed scar does not call for the introduction of a free fat graft from a distance. The skin scar is excised and the margins are undermined and retracted to expose the neighbouring deep tissue. Flaps of this tissue sufficient to meet the requirements of the case are fashioned and approximated. In some cases local flaps of this kind are made, but with

Fig. 2054.—Depressed scar treated by excision and the filling of the deep tissue defect by local fat flaps. Since the last photograph was taken the skin scar has become much less obvious.

their bases at the margins of the deep tissue defect and their distal extremities turned over into the depression and fixed by catgut sutures. A depressed scar treated in this manner is illustrated in figure 2054.

B. Bone Grafts

Although bone is occasionally employed in lieu of cartilage for restoration of nasal contour, it is seldom that the plastic surgeon is called upon to use this material except for the repair of defects in the mandible. Such defects were extremely common in early post-War work, bone having been lost as the result of gunshot wounds or following prolonged suppuration and sequestration. In civil practice one is called upon to repair losses due to old osteomyelitis, in cases of un-united fracture, and in cases in which portions of the jaw have been

removed in the treatment of malignant disease. The extent of the loss and the corresponding length of the graft required to make good that loss appear to have no bearing on the success or otherwise of the operation.

It is essential that there shall remain no trace of infection either in the region of the defect or of the external scar, or about the roots of teeth which are likely to be approached during the preparation of the bed for the graft. Teeth should be removed when necessary, and if there is doubt about the scar region the scar should be excised as a preliminary procedure. Firm fixation of fragments—of both when possible, and of the larger fragment when the other is edentulous—is important. When both fragments are edentulous, firm fixation of the graft itself to both fragments is essential, for the graft must act in such cases as the only splint available.

Perforation of the buccal muco-periosteum contra-indicates the introduction of a graft, no matter how carefully the tear is repaired by sutures. No degree of malposition of fragments precludes successful grafting, but severe displacement and extensive scar tissue between the bone ends may necessitate operation in two stages. At the first of these the fragments are freed from the mass of scar tissue and are splinted in good position. It is my practice in such cases always to approach the mandibular fragments from outside, and it is seldom that I have found it impossible to free them and place them in normal position by this route and without opening into the mouth. Occasionally, however, intra-buccal scarring is so extensive that excision of scarred muco-periosteum with plastic rearrangement is required in order *to allow the fragments to be separated and placed in correct position.* In such cases it is wise to wait at least three months before re-operating.

The smaller fragment in fractures near the angle of the mandible, which is frequently edentulous, is usually displaced upwards and rotated inwards so that its inferior border, instead of being roughly horizontal, slopes upwards and forwards. Free subperiosteal freeing of this fragment allows it to be brought down and back into correct position. In long-standing cases this may be impossible without division of the coronoid process to release the fragment from a fibrosed and contracted temporal muscle. I have never noted any disability following this procedure nor following the free separation of masseter and pterygoid muscles. These muscles undoubtedly establish fresh connections and take up their normal functions when the jaw is released from splints. The edentulous posterior fragment is maintained in good position by the bone graft itself.

The larger tooth-carrying fragment is always fixed in occlusion, beforehand if possible, by metal-cap splints provided with some bolting mechanism holding the lower teeth to the corresponding ones in the upper jaw. Where expert dental collaboration is not available, simple inter-dental wiring provides satisfactory fixation. The splint illustrated (fig. 2055) was prepared by Mr. A. L. Fraser and is the type

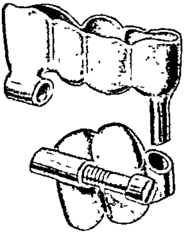

Fig 2055.—Metal-cap splint with screw employed in bone graft operations on the mandible.

used at the Ministry of Pensions Hospital, Roehampton. Such an apparatus makes for clean and firm fixation and allows of easy separation of the jaws at intervals for an estimate to be made of the firmness of union.

Technique of Bone Graft Operation

The jaw fragments are exposed through an incision planned to leave a scar line just below the line of the restored mandible. When a scar is already present, this is excised and elongated, if need be, to obtain free access to the bone ends. Skin flaps are freed for a short distance above and below, and an incision is then made through the deep tissues straight down to bone. The internal and external surfaces of the bone are cleared by a rougine. Any irregular spicules of bone are divided at their bases and carefully twisted out of their adherent deep tissues. Attempts to work completely round such projections by rougines or elevators are fraught with grave risk of opening into the mouth cavity. The ends of the fragments are trimmed with bone-cutting forceps. The posterior fragment, when unfixed by a splint, is steadied by means of a large pair of Kocher forceps clamped on it near the angle. The fragment is freed and placed in good position as already described. A saw cut is made on its outer surface about 2·5 cms. from its extremity and parallel to its cut end. This saw cut is usually made with a key-hole or nasal saw, but an electrically-driven circular saw of small dimensions (the crown

saw used by dentists) facilitates the work. The saw cut goes through the outer table only. The outer surface of bone between the freshened extremity and this saw cut is removed by driving a thin osteotome backwards from the cut extremity. Two holes are drilled through the remaining inner table, one above the other, at a distance of about 1·0 cm. Fine silver, stainless steel or phosphor-bronze wire is threaded through these holes, the loop being left on the deep surface of the bone and the ends coming out on the freshened surface. These ends are clamped and wrapped in gauze to prevent contact with skin edges.

The anterior fragment is prepared in precisely similar manner.

Difficulty may be encountered in threading back the wire suture from the deep to the superficial aspect of the bone. A tubular guide may be used for this purpose, or a needle, passed eye first from without inwards, may be threaded with the wire, which is then easily drawn through. A model is now made in sheet lead of the graft which will be required to bridge the gap and overlap the freshened surfaces of the fragments, and on this are marked the positions of the points of egress of the wire suture. Blood-vessels are ligatured and the wound is packed with a gauze swab.

Taking the Graft.

The graft is taken from the crest and outer surface of the ilium on the side of the defect, and the illustration (fig. 2056) indicates the piece of bone to be removed. The necessary cuts are usually made with thin osteotomes, though they may be made still more readily by means of a motor-driven circular saw. The removal of this portion of the ilium causes no disability or disfigurement and it interferes very little indeed with muscular attachments. The anterior superior spine is left undisturbed. Periosteum is taken with the bone. The knife is passed under the ligamentous layer on the crest and this is turned inwards as a flap. The glutei muscles are separated from the outer surface of the bone and retracted. As a rule, only one small vessel requires ligature.

The lead pattern is laid on the outer surface of the bone and its anterior, posterior, and inferior margins are outlined by cuts with a sharp osteotome. These are carried half-way through the thickness of the bone. The osteotome is then driven downwards from the mid-line of the crest, and the separation of the graft is thus completed. The separated piece of bone, grasped in Lane's bone-holding forceps, is wrapped in a warm sterile towel and transferred to a separate table for later modelling. The wound is closed in two layers—the first of catgut sutures approximating the cut gluteal fascia to the fascial flap turned up from the crest. It has been found that the extended position of the

hip gives greatest relaxation for this to be carried out, but occasionally it is necessary to vary the position of the leg during the suturing process. *The second layer consists of skin suture of ordinary type.* A rubber-dam drain is inserted at the posterior angle of the wound for forty-eight hours. The graft is trimmed of any pieces of muscle which remain attached to its outer surface, and is then cut and drilled in corres-

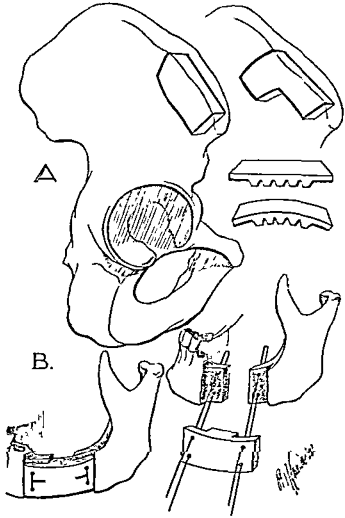

Fig. 2056.—The technique of mandibular bone-grafting. Straight, curved and angled grafts are illustrated above. *Below*, freshening of fragments and method of fixing the shaped graft by wire mattress sutures.

pondence with the fragments to which it is to be morticed. The necessary transverse cuts are made with a small saw and the cancellous bone is removed either by the same instrument or by bone-cutting forceps. The whole procedure can be done in a few minutes. The graft is held by the Lane forceps throughout and is protected carefully from contact with the skin whilst it is being placed in position in the mandibular wound.

This technique has been varied a little from time to time by drilling

the graft before removing it from the ilium, but no serious advantage is gained by this manœuvre and there is some danger of carrying the drill too deeply in one's effort to make a clean hole.

The graft is threaded on the ends of the wires, guided into position, and held there while the wire loops are tightened by twisting. The twisted ends are cut short and gently pressed into the outer surface of the graft. The deep tissue flaps are approximated over the graft by catgut sutures and the skin wound is closed by interrupted stitches of fine silkworm-gut, a small drain being inserted to guard against a blood collection which in this situation is so liable to become infected.

In cases where the angle is missing and a reasonable fragment of ascending ramus can be found and freshened, an angled graft has sometimes been cut as indicated in figure 2056. In cases where extensive portions of bone are missing from the front of the jaw, the graft may be curved to suit the chin contour by making saw cuts on its cancellous surface, similar to those made by Albee in his spine grafts, or by the excision of wedges from this surface. Multiple small wedges weaken the graft much less than fewer but more extensive ones.

I have employed a curved graft of this type 12 cms. long (i.e. about $4\frac{1}{2}$ inches) to bridge a gap extending from molar to molar region. In this case the soft tissues of the chin region had been reconstructed by a double pedicled forehead flap brought into position over marginal in-turned flaps which had restored the lining of the defect (see fig. 2065). At a later date the hair-bearing in-turned flap was removed and a new gingival sulcus was prepared by Thiersch grafting on a mould placed in front of the bone graft. This allowed a lower denture to be fitted which not only improved the contour of the chin but restored masticatory function.

T. J. D. Lane of Dublin has devised an instrument which greatly facilitates the preparation of such long curved grafts. It consists of two springy pieces of steel, between which the bone graft is placed, and which can be clamped together. Along the edge of one of these are a number of little raised ridges which prevent the graft from slipping. Before bending, cross-cuts, as already described, are made on the cancellous surface of the graft. By slowly increasing pressure made with the fingers, the graft can usually be curved or bent to the degree necessary without causing a break. If much bending or angulation is required, and more particularly in older patients, a break may and often does occur even when this instrument is employed. Such breaks can, however, be only subperiosteal in character and do not affect the final consolidation of the graft.

After-Treatment.

Drains are removed from lip and jaw wounds in forty-eight hours. Skin sutures are removed, some on the fifth and the remainder on the seventh day. Apart from ordinary oral hygiene no further after-treatment is required. Where intra-oral splinting has been impracticable every effort is made, by external bandaging, to prevent movements of the jaw. In six to eight weeks union is usually sound, and free active movements may be allowed. X-ray examination at intervals after the operation helps in estimating the progress of bony union and

Fig. 2057.—Old osteomyelitis of mandible with pathological fracture and non-union on left side. The case was treated by bone graft from ilium, and later a new gingival sulcus was constructed by a Thiersch graft applied on a mould. Both functional and cosmetic results were satisfactory.

the maintenance of good position, but clinical examination is the more certain criterion in deciding when splints may be discarded.

In most cases of mandibular bone graft a subsequent "buccal inlay" is required to reconstruct the gingival sulcus and so make it possible for the dentist to fit a denture. It is wise to wait for at least six months after the bone graft operation before carrying out this procedure in order to avoid risk of infection at the sites of wiring. Only in exceptional cases has it been necessary to remove the wire sutures at a later date.

Figure 2057 illustrates the result obtained in a case of old osteo-

myelitis with pathological fracture and non-union on the left side of the mandible. Figure 2058 is a skiagram showing the graft in position in a case in which extensive loss of bone followed a pit explosion injury.

Fig 2058.—LEFT SKIAGRAM SHOWS LOSS OF BONE ON RIGHT SIDE OF MANDIBLE FOLLOWING PIT EXPLOSION INJURY. RIGHT SKIAGRAM SHOWS RESULT OBTAINED BY ILIAC BONE GRAFT.

C. FASCIA LATA GRAFTS

In the absence of infection, fascia lata behaves excellently as a free graft. It may be used, as material having a rather firmer consistency than fat, for contour building, or it may be taken together with overlying fat for this purpose. It is used occasionally for supporting the upper eyelid, as in operations for ptosis. I, personally, reserve it almost entirely for facial paralysis cases. In such cases, even though there may still be some hope that recovery of nerve function may occur, a fascia lata sling to the angle of the mouth is well worth while. It supports the paralysed muscles and prevents damage to them by stretching during the recovery stage, and is infinitely to be preferred to any external splinting.

When paralysis is established—the face drooping and lacking any natural movement or expression, food accumulating in the lower buccal sulcus, and the unparalysed muscles of the opposite side drawing the mouth over in disfiguring fashion whenever movement is attempted—fascia lata slings to the upper lip, the lower lip, and the angle of the mouth give both cosmetic and functional improvement.

Figure 2059 indicates clearly the technique employed. Short incisions are made on the unparalysed side of the philtrum in the upper lip and parallel with the lip margin at a corresponding point in the lower lip. A small curved incision is made just outside the angle of the mouth on the paralysed side. The edges of these incisions are undermined for a short distance in order to expose the underlying muscle-fibres.

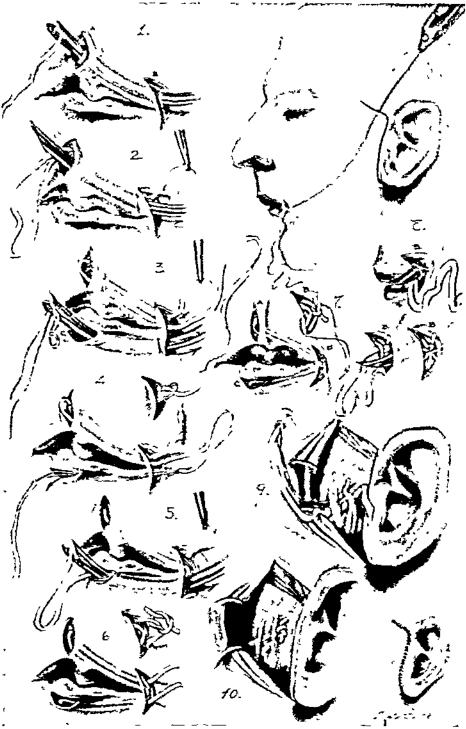

Fig. 2059.—The technique of the fascia lata sling operation for facial paralysis.

A special trocar needle (Blair-Smith) is inserted at *B* and passed in the deep tissues of the upper lip to emerge at *A*. A fascia lata strip is drawn back to *B* and its end is held in pressure forceps. The needle is again inserted at *B* and passed more superficially and nearer to the lip margin, to emerge again at *A*. The other end of the fascia strip is now drawn back to *B*, ready for use on the lower lip. It is essential that the fascia loop so formed should have a firm hold of the unparalysed muscle exposed in the lip incision *A*.

The needle is now passed from *B* in a superficial plane and near to the lower lip margin, and emerges at *C*. It draws back to *B* a loop of silkworm-gut. This loop is knotted over the free end of the fascia strip and serves to draw it through to *C*. The needle is again passed, this time on a deeper plane and picking up unparalysed muscle before emerging from the lip incision. The end of the fascia strip is drawn back to *B*. A strand of silkworm-gut is passed under the fascia loop at *B* to act as a guide later in the operation. The free ends of the strip are knotted and drawn taut enough to contract slightly the paralysed half of the mouth. The knot is reinforced by fine silk sutures which should pick up only a few fibres of the strand. The incisions in the lips are then closed by fine sutures.

An incision is now made precisely as for cosmetic face-lifting in the temporal and pre-auricular regions, and the skin of the cheek is undermined superficially sufficiently to expose an area of the parotid fascia below the zygoma. The trocar needle is passed subcutaneously from the depths of this wound to emerge in the incision at the angle of the mouth where, following the silkworm-gut guide, it passes through the double loop of fascia controlling the lips. One end of a new strip of fascia is caught up in the needle and drawn back to the temporal region. The needle is passed a short distance from its previous track in the cheek and emerges again at *B* to draw back the other end of the cheek loop. This loop may with advantage be made to pick up in its course deep tissues near the angle of the mouth. The wound at *B* is then sutured.

The free ends of the cheek loop are now threaded on J. T. D. Lane's fascia needles and woven into the parotid fascia. They are drawn sufficiently tight to over-correct the position of the angle of the mouth and are then knotted. The knot is reinforced by one or two fine silk sutures. The skin flap is drawn upwards and backwards and the overlap is removed (see fig. 2114). Interrupted sutures close this wound.

As a rule, it is necessary to carry the skin incision around the ear lobule attachment and backwards in the retro-auricular groove for a

has been carried out in conjunction with that described for the support of the mouth and cheek.

It has not been thought necessary to describe the technique employed in obtaining fascia strips from the thigh. An endless variety of fascia "strippers" is available. I habitually use that devised by Lane of Dublin—the Meath Hospital fasciatome.

D. CARTILAGE GRAFTS

Cartilage has proved a most useful material for contour restoration, particularly in the nose where support rather than the mere filling in of a contour defect is required. It may be obtained in ample quantity from the region of the costal margin, and it can be readily cut to any desired size and shape. Cartilage is one of the few body materials which can be transplanted successfully from one individual to another. It need hardly be mentioned that no such transfer should be attempted without careful preliminary blood tests, lest latent disease be transferred from donor to recipient.

No detailed description need be given of the operation for removal of the cartilage. That portion of the 7th right costal cartilage ascending to the sternum is the material usually removed, and it is approached through a rectus-splitting incision (see fig. 2084). The free extremity of the 8th costal cartilage is almost always exposed in the wound, and a varying length of this is commonly removed to be kept as spare material. An oblique incision following the costal margin provides a more difficult approach but gives a less obvious scar line, and is sometimes chosen for this reason or when only a small piece of cartilage is required.

When larger masses of cartilage are required, the area of fusion of cartilages is readily exposed. When removing such larger pieces in this region care must be taken to prevent damage to the underlying pleura. At the end of the operation all spare cartilage likely to be of further use in case of infection and extrusion of the first graft, or in case further building up is required later on, is buried subcutaneously in the abdominal wall. From this situation it is readily removed under local anæsthesia and with a minimum of disturbance to the patient.

After removal of cartilage from the ribs the patient experiences considerable discomfort, particularly on moving, for 24–48 hours. Much can be done to minimise this by careful strapping of the wound with elastic adhesive strapping, much in the same way as fractured ribs are immobilised. As already mentioned, rib cartilage finds its chief field of usefulness in building forward and supporting the depressed bridge of the nose. It is employed for the same purpose in

reconstructive rhinoplasty to support the soft parts which have been restored by forehead flap or other means. Cartilage has one bad fault, namely, its tendency to curve, and this has led many workers to abandon it in favour of bone. Much can be done to prevent this late distortion by carefully removing perichondrium, and in some cases, when a two-stage operation is essential, the cartilage may be taken before it is required, denuded of perichondrium, and buried in the abdominal wall. When required, any curving which has occurred is corrected in the shaping of the graft.

The larger masses of cartilage mentioned are found useful in building up malar contour where there has been loss of bone, and for filling depressions in the forehead or defects in the skull. When only small contour defects are to be treated, sufficient cartilage for the pur pose may be obtained either from the upper part of the alar cartilages of the nose, the removal usually improving the shape of the nose tip, or from the ear. Cartilage from this latter source is particularly suitable for supporting the drooping lower eyelid in facial paralysis.

The technique of the nasal cartilage graft operation is described later (see fig. 2084).

CHAPTER IV

Flaps

Advancement or Sliding Flaps

Although not usually visualised as such, the areas of skin which are undermined from the margins of a defect and advanced and approximated to cover it, constitute flaps which fall into this category. All reasonably small defects, such as those produced by the excision of hairy or pigmented moles, are closed in this manner. The skin incisions extend beyond the mole in elliptical form in order to facilitate closure without protrusion or dimpling at the extremities of the suture line. The procedure may be modified to meet the requirements of more extensive skin blemishes. Only a part of the undesired area is removed at the first stage; the wound margins are undermined and approximated, and a scar line is left within the confines of the area itself. After a delay of some months, during which the surrounding skin is massaged, the remainder of the area is excised in elliptical fashion, and it is usually found that the undermined skin edges can then be approximated without undue tension. In some situations the complete excision of quite large skin areas can be achieved in several stages of this kind with the obvious advantage of leaving a single linear scar line. The excisions are carefully planned so that the final scar may be as far as possible in a natural skin fold.

Where the skin available is limited, as on the leg, yet it is essential that a skin defect shall be covered by healthy full-thickness skin bearing some fat, lateral relaxation incisions may be made. These allow of easy approximation of the sliding flaps without tension. The gaps produced at the sites of the relaxation incisions may be covered immediately by Thiersch graft or left to epithelialise spontaneously.

Rotation Flaps

These were first described and extensively employed by Esser. A large area of skin adjoining a defect is partly or completely undermined. Carefully planned incisions allow this flap, while retaining a broad base, to rotate into position over the defect. Closure of th incision by interrupted sutures allows of even distrib of tensio Figure 2061 illustrates a case in which the skin of the

Fig. 2061.—Record of a case in which a large rotation flap was employed to cover the defect in the infra-orbital region produced by the excision of a capillary nævus.

Fig. 2062.—Record of a case in which a flap transposed from below the mandibular margin to a vertical position on the cheek, was used to cover the defect produced by excision of an *epitheliomatous ulcer in an old lupus scar*

clockwise to fill a triangular defect in the infra-orbital region produced by the excision of a very disfiguring nævus. It will be seen that the secondary scarring necessarily produced has been arranged to fall in situations where it is barely visible.

Transposed Flaps

Into this category fall those flaps, deliberately formed from the adjacent skin, whose long axis is made in a direction roughly at right angles to the long axis of a defect. Many such flaps are employed for the immediate closure of defects about the mouth and cheek.

Figure 2062 illustrates a case in which such a flap was cut from the skin immediately below the mandibular margin and swung up to cover the raw surface produced by the excision of an epitheliomatous area which had developed in an old variously-treated patch of lupus.

Figure 2063 illustrates a case in which a nasal defect, produced by the excision of a rodent ulcer which had resisted treatment by radium,

Fig. 2063.—A case illustrating the use of a transposed flap from the naso-labial fold for the repair of a defect produced by the excision of a rodent ulcer which had resisted treatment by radium. The base of the flap was above, and its lower (distal) portion was in turned to provide lining for the defect.

was repaired by a long narrow flap from the naso-labial cheek fold. The base of the flap was above, and its distal portion was folded upwards to provide lining for the defect.

Triangular flaps of this type are commonly shifted from above to below the angle of the mouth. When obtained from the naso-labial fold region, the resulting scar is seldom noticeable.

Flaps from the same region may be cut of full thickness, carrying skin, muscle and mucosa, and these supply particularly valuable reconstructive material (fig. 2064).

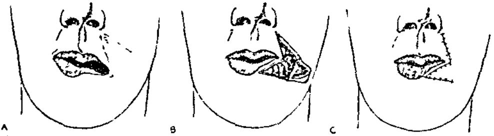

FIG. 2064.—FULL-THICKNESS TRANSPOSED FLAP FROM ABOVE TO BELOW THE ANGLE OF THE MOUTH.

Bridge or Pedicled Flaps

The most commonly used flap of this type is that cut from the forehead in nasal reconstruction by the so-called Indian method (see fig. 2072). Such a flap has a pedicle which overlaps the skin between donor and recipient areas and which is retained only so long as it is necessary to maintain the nutrition of the flap while it is establishing its own connections with the recipient area. In some situations, in order to diminish exposed raw surface, the pedicle may be tubed, i.e., its margins may be approximated by sutures. The pedicle of such a flap may be safely divided and returned in 2–3 weeks according to the vascularity of the area to which the flap is attached and according to the extent of this attachment.

A forehead flap may have its pedicle based on the superficial temporal vessels of one side, or the whole of the skin of the forehead may be swung down like a bucket handle on two pedicles of this type. The former is useful when the nose and part of the cheek have to be reconstructed, the latter is particularly useful for reconstruction of the chin and lower lip regions.

The diagrams in figure 2065 were drawn from an actual case in which the chin region was built up by this means. At a later stage of treatment a curved bone graft, introduced between lining and covering skin, restored the continuity of the mandible, while still later the hairy in-turned skin was removed and replaced by Thiersch graft. At the same operation a new gingival sulcus was constructed in front of the

ingenious and most satisfactory means of transporting skin from a distance. Designing flaps of precisely similar type, independently and in the same year, he immediately found many new applications for the principle involved and rapidly extended their field of usefulness in all branches of reconstructive work.

By means of such flaps large areas of skin may be transported with safety from the chest or abdominal wall to situations as far distant as

Fig 2067.—A tubed pedicle flap prepared on the chest wall and transferred in stages to reconstruct an extensive cheek defect.

the sole of the foot or the top of the head. An intermediate attachment to the wrist is the most suitable method of transfer (where direct transfer is impossible), but in selected cases the flap may be moved in several stages in " caterpillar " fashion.

The details of preparation and transfer are well illustrated in figure 2066, while figures 2067 and 2068 illustrate typical results obtained by direct transfer of tubed pedicle flaps from chest to face.

It is unwise to prepare a tubed pedicled flap materially longer than

6 inches or narrower than $2\frac{1}{2}$ inches. Greater length may be obtained by extending the flap after a short delay. The defect produced by removal of such an area of skin can be closed by approximation after undermining of wound edges.

It is wise to drain both the abdominal (or chest) wound and the tube itself for forty-eight hours.

If a wider flap is required, the abdominal or chest wound is covered immediately by Thiersch grafts, and in this way one of the greatest

Fig. 2068.—A tubed pedicle flap prepared on the chest wall and transferred in stages to fill the defect produced by the excision of an angioma of the cheek which had resisted prolonged treatment by other means.

advantages of the flap is maintained, namely, the leaving of no raw surface for painful dressing or for infection.

It should be stressed that the skin tube itself *is* the flap; it *is not* the pedicle on which a flap of skin extending beyond one or other attached end is to be transferred. Any attempt to carry skin in the latter manner is fraught with extreme risk of necrosis unless the area of skin beyond the tube is first delayed in the manner already described.

Special applications of the tubed pedicle flap for nose reconstruction are illustrated in figures 2076 and 2077.

CHAPTER V

Types of Repair

Some *general remarks on this subject would appear to be not out of* place at this point.

In planning reconstructive work about the nose and mouth, more particularly at the time of a destructive operation called for by the presence of *a malignant growth, a careful decision must be made as to* the advisability of carrying out primary or secondary repair. The dangers of the former may be briefly tabulated as follows:

(1) The destructive operation is likely to be carried out in less radical and satisfactory manner if closure of the defect he is producing is constantly in the thoughts of the operator.

(2) The shifting of local flaps to fill in the defect opens up new tissue to infection from the cavity involved, and is likely to increase the danger of spread of malignant disease.

(3) The available skin bordering on the defect is frequently unsuitable plastic material. It may be scarred or may have been partly devitalised by X-ray or radium treatment of the malignant growth or other disease.

(4) Except when the defect produced is small, local flaps are seldom sufficient to make a really complete replacement of removed parts, and the reconstruction is likely to be a disappointing one from the cosmetic point of view.

(5) It is seldom possible to be certain of the complete removal of a malignant growth. Primary repair gives no opportunity of judging this and may [illegible]ome extremely complicated by recurrences *which, being* [illegible] *[illegible]eedingly difficult to treat.*

Primary repair may be [illegible] [illegible]nce, however, from the psycholog[illegible] [illegible] of view [illegible]l strain placed on a patient w[illegible] [illegible]stance, [illegible] weeks dribbling saliva from a la[illegible] into th[illegible] [illegible]ive due consideration. In this c[illegible] [illegible]y be [illegible] expended on the [illegible] patient's comfort.

The advantages of secondary repair may be similarly tabulated:

(1) The destructive operation may be carried out in really radical manner, the surgeon being unhampered by thoughts of the reparative procedure.
(2) Sound healing of the borders of the defect gives a greater field of plastic material, and leaves marginal skin flaps available for turning in to reconstruct the lining of the defect.
(3) A period of observation for local recurrences is given. Such are unhidden and may receive appropriate treatment immediately.
(4) Time is given to plan deliberately and carefully a replacement by ample healthy material brought from a distance where any secondary deformity is of no moment or is completely hidden.

Secondary repair, however, usually necessitates a series of operations extending over a considerable period of time. In spite of this disadvantage my inclination is always towards this type of repair, for I have encountered no more distressing cases than those in which patients have been called upon to submit to a second destructive operation. Final repair in such circumstances becomes a very complicated procedure.

In all such cases as those under discussion it would seem best to arrange for close collaboration between the general surgeon and the plastic surgeon. The latter will encourage the former to be radical in his removal and will guide him in how to treat the margins of the defect so as to facilitate repair at a later date. In many cases he will be able to carry out the first stage of the reconstructive procedure by preparing a tubed pedicle flap on the chest or abdominal wall at the same operation.

Because of my firm opinions on this subject I do not propose to include descriptions of primary reparative procedures. Countless skin and full-thickness flaps falling into the various categories already mentioned have been designed, and excellent descriptions of these will be found in *Les Autoplasties*, published in 1907 by Nelaton and Ombrédanne.

CHAPTER V

Types of Repair

Some general remarks on this subject would appear to be not out of place at this point.

In planning reconstructive work about the nose and mouth, more particularly at the time of a destructive operation called for by the presence of a malignant growth, a careful decision must be made as to the *advisability of carrying out primary or secondary repair.* The dangers of the former may be briefly tabulated as follows:

(1) The destructive operation is likely to be carried out in less radical and satisfactory manner if closure of the defect he is producing is constantly in the thoughts of the operator.
(2) The shifting of local flaps to fill in the defect opens up new tissue to infection from the cavity involved, and is likely to increase the danger of spread of malignant disease.
(3) The available skin bordering on the defect is frequently unsuitable plastic material. It may be scarred or may have been partly devitalised by X-ray or radium treatment of the malignant growth or other disease.
(4) Except when the defect produced is small, local flaps are seldom sufficient to make a really complete replacement of removed parts, and the reconstruction is likely to be a disappointing one from the cosmetic point of view.
(5) It is seldom possible to be certain of the complete removal of a malignant growth. Primary repair gives no opportunity of judging this and may become extremely complicated by recurrences which, being hidden, are exceedingly difficult to treat.

Primary repair may be of great importance, however, from the psychological point of view, and the physical strain placed on a patient who, for instance, must go about for weeks dribbling saliva from a large opening into the mouth, should receive due consideration. In this connection it may be mentioned that a little ingenuity expended on the dressing of such cases may add materially to the patient's comfort.

The advantages of secondary repair may be similarly tabulated:

(1) The destructive operation may be carried out in really radical manner, the surgeon being unhampered by thoughts of the reparative procedure.
(2) Sound healing of the borders of the defect gives a greater field of plastic material, and leaves marginal skin flaps available for turning in to reconstruct the lining of the defect.
(3) A period of observation for local recurrences is given. Such are unhidden and may receive appropriate treatment immediately.
(4) Time is given to plan deliberately and carefully a replacement by ample healthy material brought from a distance where any secondary deformity is of no moment or is completely hidden.

Secondary repair, however, usually necessitates a series of operations extending over a considerable period of time. In spite of this disadvantage my inclination is always towards this type of repair, for I have encountered no more distressing cases than those in which patients have been called upon to submit to a second destructive operation. Final repair in such circumstances becomes a very complicated procedure.

In all such cases as those under discussion it would seem best to arrange for close collaboration between the general surgeon and the plastic surgeon. Because of my firm opinions on this subject I do not propose to include descriptions of primary reparative procedures. Countless skin and full-thickness flaps falling into the various categories already mentioned have been designed, and excellent descriptions of these will be found in *Les Autoplasties*, published in 1907 by Nelaton and Ombrédanne.

CHAPTER VI

Operations on the Nose

A. Reconstructive Rhinoplasty

The whole history of plastic surgery is intimately linked up with this subject. It would serve no useful purpose, however, to discuss the endless variety of methods which have been advocated or practised and I shall describe only the routine procedure which I employ. This is based on the so-called Indian method, to the development of which Keegan and Smith contributed so much of the pioneer work. It will be readily seen that this can be modified to meet the requirements of almost any defect in this region. It is quite true that very satisfactory prosthetic appliances, fashioned in metal or pliable material, can be made to hide defects in the external nose. These may be attached to spectacle frames or fixed by glue so that the line of junction between artificial and real is barely noticeable. They are, however, expensive in first cost and require renewal or renovation at frequent intervals, while for the ordinary working man who must submit them to the effects of dirt and weather they are, in my opinion, impracticable. Even at their best they cannot supply that sense of security which is given by a nose reconstructed in " flesh and blood," a feature which, even if not perfect in every detail, becomes essentially a part of its possessor. When it is realised that a few weeks' hospital treatment can transform a hideous creature, shunned by everyone, hiding his disfigurement by bandage or ill-fitting artificial piece, into a normal-looking individual, eliciting, at the most, interested observation; and when it is realised that a little further operative work, carried out some two to three months later, can add to the nose shapeliness and character and obliterate those minor defects in restoration which elicited even such observation, it must be conceded that there is every reason for preferring reconstruction to the camouflage of the artificial piece.

The chief essential, still sometimes overlooked, in nose reconstruction is the supply of adequate lining material. In post-War cases this could usually be obtained in sufficient quantity by turning in flaps based on the margins of the defect; but in the majority of cases

encountered in civil practice, the skin in the neighbourhood of the defect is fibrosed or atrophic as the result either of the original disease (e.g., lupus or rodent ulcer) or of its treatment. Even should such material survive, it is liable to undergo considerable shrinkage, either because of its initial poverty of nutrition or on account of its necessary rotation through almost 180 degrees.

For many years now it has been my practice to rely more and more on the forehead flap for the provision of both covering and lining. This plan is by no means a new one, for it was described by Gandolfi and Bertani in 1845 and was rediscovered thirteen years later (1858) by Pétrali, who relates how he came upon it by chance whilst idly folding a mulberry leaf in his fingers. As the result of attempts to estimate beforehand, by means of patterns and models, the quantity of skin required to supply sufficient lining material and at the same time provide something adequate for the columella and "septum," I have come to in-fold the flap to a greater extent than is usual. The shape and size of flap required in any particular case can be planned beforehand by patterns cut in chamois leather or in thin sheet lead. The former material simulates closely the skin, while the latter has the advantage of retaining the form into which it is moulded. Either can be boiled and used during the actual operation.

It may be noted here that a certain amount of hair on the in-turned portion of the flap is not seriously troublesome; this allows one to carry the forehead incision outlining the flap to a reasonable extent into the downy skin of the anterior temporal region.

Preparation of Defect.

The nose stump is prepared (fig. 2069) by incisions placed near the margin of the defect in such a manner as to leave a narrow frill of skin on the inner (lining) side to hold the sutures which will unite it later to the in-turned edges of the forehead flap. These incisions are carried down the lateral margins of the defect to points on the upper lip chosen for the basal attachments of the new alæ. The skin of the cheek is undermined slightly to facilitate later suture to the flap. The anterior border of the septal remains is incised, and the mucosa is reflected for a short distance on each side. This septal incision is carried down on to the lip where an area is prepared, by removal of a small piece of skin or scar, for the attachment of the columella. Any scarred skin covering the upper part of the nose remains is dissected off and discarded.

When no septal partition is present it is an advantage to retain and turn down a narrow flap from above, and to suture its distal border to a

small flap turned upwards from the centre of the lip (fig. 2070). This flap is in no way comparable to the hooded lining flap frequently employed in post-War injuries. It does not form any material part of the lining of the new nose, but makes a useful backing for the new "septum" and gives something reasonably fixed to which may be sewn the central part of the in-turned portion of the forehead flap.

The aim of this preparation of the nose defect is, in all cases, to

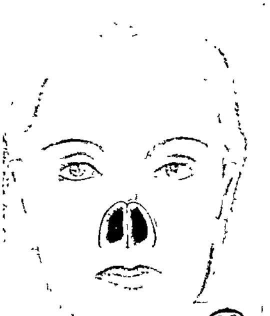

Fig 2069.—Preparation of nose stump for reception of forehead flap. The area of skin or scar usually removed from the upper part of the nose is not indicated.

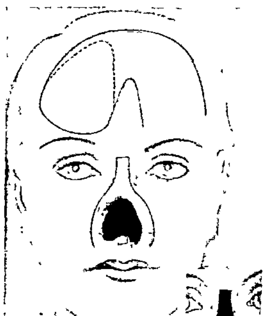

Fig 2070.—Preparation of nose stump when no septal partition remains. Lines of incision for raising flap and pedicle are shown on forehead.

produce two separate airways bounded by material capable of holding sutures. These apertures lie in the coronal plane or slope forwards from that plane above, according to the greater or less degree of nose destruction. When they lie flush with the rest of the face, the reconstruction calls for the maximum of in-turning of the flap, while this requirement diminishes in proportion as their slope forwards is more marked. When the margins of the nose defect are unhealthy, e.g., the site of ulceration or keratosis, all diseased material is excised and the remaining edges are split for a short distance to separate their lining and covering

constituents. It will thus be seen that a reconstruction operation *may* follow immediately upon a destructive one, for a healthy-margined defect may be produced by wide removal of such lesions as rodent ulcer. It is the part of wisdom, however, in such cases to separate these operative procedures, sewing mucous membrane to skin around the defect at the close of the destructive procedure and waiting for a

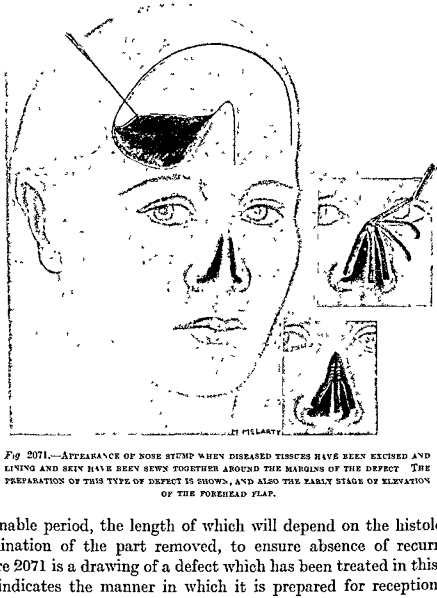

Fig 2071.—APPEARANCE OF NOSE STUMP WHEN DISEASED TISSUES HAVE BEEN EXCISED AND LINING AND SKIN HAVE BEEN SEWN TOGETHER AROUND THE MARGINS OF THE DEFECT THE PREPARATION OF THIS TYPE OF DEFECT IS SHOWN, AND ALSO THE EARLY STAGE OF ELEVATION OF THE FOREHEAD FLAP.

reasonable period, the length of which will depend on the histological examination of the part removed, to ensure absence of recurrence. Figure 2071 is a drawing of a defect which has been treated in this way, and indicates the manner in which it is prepared for reception of a forehead flap.

Raising of Forehead Flap.

When the preparation of the defect is completed, a pattern of the requisite forehead flap is made, or one previously prepared is tried in

position and given any final trimming which proves necessary. The pattern is opened out and placed in such a position on the forehead as will permit of the fashioning of a pedicle which will allow it to reach its destination without undue tension (see figs. 2070 and 2071).

The sickle-shaped pedicle (so-called "up and down"), first suggested by Gillies, gives the best provision for this requirement, but *occasionally a horizontally-disposed pedicle and flap must be employed* in order to avoid hair-bearing skin on the new nose. Careful orientation of flap and pedicle is of paramount importance; it is distressing in the extreme to find that a pedicle has been cut which will not allow the flap to reach its destination. A trial should always be made with a piece of ribbon gauze or tape held along the line of the proposed incisions and brought down to the more distant points on the nose defect. Once the positions for the flap and pedicle have been accurately estimated (they may be marked out, if desired, by pen and ink), outlining incisions are made and the raising of the flap is proceeded with. The edges of the flap are handled with care, fine hooks being employed in preference to dissecting forceps. The distal portion which is to be in-turned is cut reasonably thin, superficial to the frontalis muscle, but once this portion is passed the separation is deepened to the plane of areolar tissue immediately superficial to the pericranium. The pedicle may be raised by blunt dissection with scissors or gauze, but care should be taken to avoid trauma to its vessels on the one hand, and exposure of bone on the other.

Hæmorrhage, which is liable to be free, is best controlled by pressure exerted by an assistant on the eyebrow margin and over the superficial temporal vessels. No form of tourniquet or scalp-forceps has proved satisfactory.

When the flap and pedicle have been freed, marginal bleeding vessels *on both flap and scalp are picked up in artery forceps and tied. Iced* saline compresses help to arrest oozing from the scalp defect, but must not be used on the flap, which is temporarily covered by gauze wrung out of warm saline. The flap illustrated is a fairly typical one for a case in which the nose loss is extensive. It will be noted that it has neither indentations nor narrow prolongations, and therefore possesses as perfect a blood supply as possible to all parts. The older method of making a small prolongation for the columellar region frequently led to loss of this most important part of the reconstruction, a calamity which ruined an otherwise excellent new nose. The pedicle must be kept wide, seldom narrower than the widest part of the flap.

In cases where the viability of tissues is low, as in old people, the

forehead flap may be "delayed," that is, it may be outlined by incisions but not raised at the first operation. In other cases it may be deemed advisable to raise the flap and pedicle, or some portion of them, and return them to the forehead for a short period before submitting the pedicle to the rotation necessary to bring the flap to the nose defect. Such intermediate stages, and indeed the whole reconstruction, can be carried out under local anæsthesia. This materially diminishes hæmorrhage but introduces the possibility of producing thrombosis of the main vessels of the pedicle. It may not be out of place to mention at this point that venous and possibly also lymphatic drainage of a flap is of equal importance to arterial blood supply. Indeed, in most cases of gangrene of a flap the cause may be traced to deficient venous drainage leading to congestion and thrombosis. A white flap is infinitely to be preferred to a blue one.

The distal margin of the forehead flap is now accurately sutured to the lining margins of the airways, a guide suture being first placed between its mid-point and the proposed lip columella junction. Suturing is continued laterally from this central point until the alar bases are reached, when it is continued upwards between the cheek skin edges and the lateral margins of the covering portion of the flap. On the inside of the new nose, catgut sutures, either interrupted or continuous, are employed; on the outside, interrupted silkworm-gut sutures are used.

As the suturing progresses, so the tip portion of the nose takes shape, and it is always particularly gratifying to note the way in which the tip of the nose gradually acquires very natural protrusion and the new nostril margins take on a rolled appearance (fig. 2072). Mattress sutures may be passed between lining and covering to accentuate *supra-alar hollowing*, while a similar suture passed *across the bridge* line may be employed to maintain prominence in this region and prevent hæmatoma formation. Such sutures introduce some risk of interfering with blood supply to the more distal parts of the flap. They are frequently left untied at the operation, to be tightened snugly forty-eight hours or so later if the condition of the flap warrants it.

Gentle packing of the new nostrils helps to prevent accumulation of blood between lining and covering, and so preserves their shape. Rubber tubes may be introduced for this purpose but are more liable to cause pressure necrosis. The raw surface on the forehead may be covered immediately by a Thiersch graft or may be dressed with tulle gras or ambrine. Care must be taken that the bandage holding the dressings in this region causes no pressure on the edge of the pedicle.

External sutures are removed from the nose in about five days.

position and given any final trimming which proves necessary. The pattern is opened out and placed in such a position on the forehead as will permit of the fashioning of a pedicle which will allow it to reach its destination without undue tension (see figs. 2070 and 2071).

The sickle-shaped pedicle (so-called "up and down"), first suggested by Gillies, gives the best provision for this requirement, but *occasionally a horizontally-disposed pedicle and flap must be employed* in order to avoid hair-bearing skin on the new nose. Careful orientation of flap and pedicle is of paramount importance; it is distressing in the extreme to find that a pedicle has been cut which will not allow the flap to reach its destination. A trial should always be made with a piece of ribbon gauze or tape held along the line of the proposed incisions and brought down to the more distant points on the nose defect. Once the positions for the flap and pedicle have been accurately estimated (they may be marked out, if desired, by pen and ink), outlining incisions are made and the raising of the flap is proceeded with. The edges of the flap are handled with care, fine hooks being employed in preference to dissecting forceps. The distal portion which is to be in-turned is cut reasonably thin, superficial to the frontalis muscle, but once this portion is passed the separation is deepened to the plane of areolar tissue immediately superficial to the pericranium. The pedicle may be raised by blunt dissection with scissors or gauze, but care should be taken to avoid trauma to its vessels on the one hand, and exposure of bone on the other.

Hæmorrhage, which is liable to be free, is best controlled by pressure exerted by an assistant on the eyebrow margin and over the superficial temporal vessels. No form of tourniquet or scalp-forceps has proved satisfactory.

When the flap and pedicle have been freed, marginal bleeding vessels on both flap and scalp are picked up in artery forceps and tied. Iced saline compresses help to arrest oozing from the scalp defect, but must not be used on the flap, which is temporarily covered by gauze wrung out of warm saline. The flap illustrated is a fairly typical one for a case in which the nose loss is extensive. It will be noted that it has neither indentations nor narrow prolongations, and therefore possesses as perfect a blood supply as possible to all parts. The older method of making a small prolongation for the columellar region frequently led to loss of this most important part of the reconstruction, a calamity which ruined an otherwise excellent new nose. The pedicle must be kept wide, seldom narrower than the widest part of the flap.

In cases where the viability of tissues is low, as in old people, the

forehead flap may be "delayed," that is, it may be outlined by incisions but not raised at the first operation. In other cases it may be deemed advisable to raise the flap and pedicle, or some portion of them, and return them to the forehead for a short period before submitting the pedicle to the rotation necessary to bring the flap to the nose defect. Such intermediate stages, and indeed the whole reconstruction, can be carried out under local anæsthesia. This materially diminishes hæmorrhage but introduces the possibility of producing thrombosis of the main vessels of the pedicle. It may not be out of place to mention at this point that venous and possibly also lymphatic drainage of a flap is of equal importance to arterial blood supply. Indeed, in most cases of gangrene of a flap the cause may be traced to deficient venous drainage leading to congestion and thrombosis. A white flap is infinitely to be preferred to a blue one.

The distal margin of the forehead flap is now accurately sutured to the lining margins of the airways, a guide suture being first placed between its mid-point and the proposed lip columella junction. Suturing is continued laterally from this central point until the alar bases are reached, when it is continued upwards between the cheek skin edges and the lateral margins of the covering portion of the flap. On the inside of the new nose, catgut sutures, either interrupted or continuous, are employed; on the outside, interrupted silkworm-gut sutures are used.

As the suturing progresses, so the tip portion of the nose takes shape, and it is always particularly gratifying to note the way in which the tip of the nose gradually acquires very natural protrusion and the new nostril margins take on a rolled appearance (fig. 2072). Mattress sutures may be passed between lining and covering to accentuate supra-alar hollowing, while a similar suture passed across the bridge line may be employed to maintain prominence in this region and prevent hæmatoma formation. Such sutures introduce some risk of interfering with blood supply to the more distal parts of the flap. They are frequently left untied at the operation, to be tightened snugly forty-eight hours or so later if the condition of the flap warrants it.

Gentle packing of the new nostrils helps to prevent accumulation of blood between lining and covering, and so preserves their shape. Rubber tubes may be introduced for this purpose but are more liable to cause pressure necrosis. The raw surface on the forehead may be covered immediately by a Thiersch graft or may be dressed with tulle gras or ambrine. Care must be taken that the bandage holding the dressings in this region causes no pressure on the edge of the pedicle.

External sutures are removed from the nose in about five days.

Mattress sutures must be carefully watched lest they begin to cut in and produce necrosis.

Ten to fourteen days after the first-stage operation, the pedicle is divided from the flap. The cut edge of the flap is trimmed and sutured

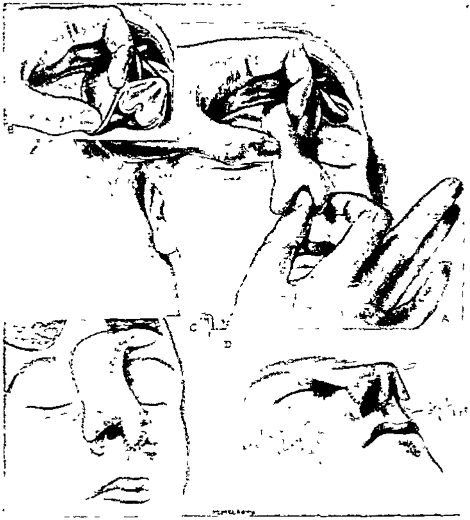

Fig. 2072.—The application of the forehead flap to the nose defect.

B. Flap rotated to show nature of in folding.
C. Suturing of flap to defect has been completed on the left side. The in turned part of the flap is being sutured to the lining margin of the right airway.
D. Suturing completed. Mattress suture passed across tip of nose but not tied.

in position on the nose. A warning should be given against leaving too little skin in the flap: *it is wiser to leave too much to be trimmed to suit the defect, which is clearly visible only after division of the pedicle, than to return to the forehead even a small area of skin which one has planned so carefully to leave behind in the new nose.*

The pedicle is cleared of granulations both on its deep surface and on its edges by gentle scraping. The corresponding portion of the raw surface on the forehead is similarly cleared of granulations, and the pedicle edges are sewn back in normal position on the scalp.

When the forehead raw surface has been grafted at the first stage,

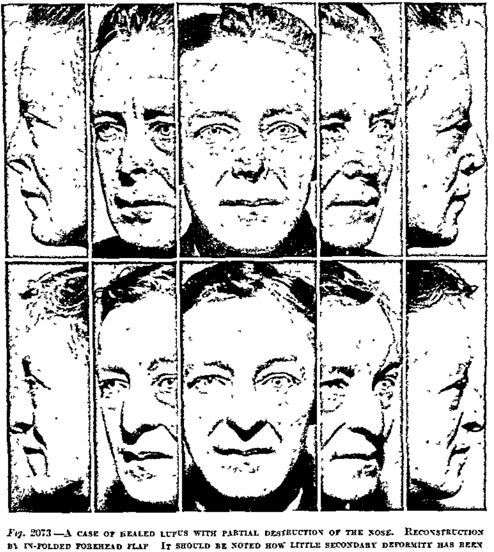

Fig. 2073.—A CASE OF HEALED LUPUS WITH PARTIAL DESTRUCTION OF THE NOSE. RECONSTRUCTION BY IN-FOLDED FOREHEAD FLAP. IT SHOULD BE NOTED HOW LITTLE SECONDARY DEFORMITY HAS BEEN PRODUCED IN THE FOREHEAD REGION.

some portion of the graft must be removed to accommodate the returned skin. If grafting has not been carried out at the first stage, the granulations may be shaved from the raw surface which remains after the return of the pedicle, and a Thiersch graft may now be applied. As raw surfaces have been exposed for some time, and infection of a mild type is therefore to be expected, it is preferable to defer grafting, place a drain under the pedicle, and apply a hot boracic

fomentation over all. Seven to fourteen days later, when healthy granulations are present, any remaining raw surface can be grafted under local anæsthesia by either Thiersch or Wolfe graft: the latter gives the more satisfactory cosmetic result. The patient is ready for discharge from hospital some 7–14 days later.

Any limited patch of hairs on the skin of the new nose, unavoidable

Fig. 2074.—A case of partial destruction of the nose due to lupus. Reconstruction by in-folded forehead flap.

in some cases where the forehead is unduly narrow, may be treated by electrolysis.

Figures 2073–2075 are records of cases treated by this method.

When the skin of the new nose has become soft and supple, definition and support may be given to the bridge line by means of a hinged cartilage graft. This is introduced via a central columellar incision and, because of the septal reconstruction given by this method of rhino-

plasty, ample room is available for the accommodation of the important columellar strut (see fig. 2084). In earlier nose reconstruction work it was customary to insert a cartilage graft in suitable position under the skin of the forehead some weeks before the forehead flap was moved. Alternatively, similar struts of cartilage were implanted under flaps which it was planned to turn in for lining the new nose with the idea of giving support to these flaps in their new position. Neither of these procedures is recommended. The latter is unnecessary, and with the

Fig 2075.—A case of chronic ulceration at the site of old lupus treated by X rays. The affected area was widely excised and the defect repaired immediately by forehead flap.

former the bridge is almost invariably incorrectly placed. It is considered a much wiser policy to reconstruct the nose in soft tissues of ample dimensions and to add the supporting structures when these, safely growing in their new position, have been rendered free of all induration by massage. Only in this way can precise definition of the bridge line and adequate support of the tip be provided.

When the degree of nose loss is extreme, a compromise must be made in regard to lining, the upper part being provided by in-turned flaps from the margins of the defect and the lower part by the forehead flap. In cases where no local material is available, the forehead flap

may be partly or wholly lined by Thiersch or Wolfe graft at a preliminary stage before it is swung down from the forehead. In exceptional cases superimposed flaps may be required, lining being provided by a tubed pedicle flap from the chest and covering by a forehead flap. In cases in which the forehead skin is scarred or when it is particularly desired to avoid producing scars in this region, a new nose may be reconstructed by means of a tubed pedicle flap transferred directly from the chest wall (fig. 2076). I have found an abdominal tubed pedicle flap, about 5 inches by 3 inches, particularly useful for nose reconstruction in these circumstances. The flap is prepared on the left lower quadrant of the abdominal wall. After a minimal interval of

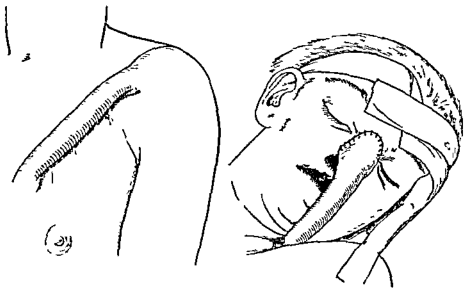

Fig. 2076.—Drawings from a case record illustrating the direct transfer of a pectoral tubed pedicle flap for reconstruction of the nose.

six weeks, during the latter half of which the patient may be out of hospital, the lower end of the flap is divided and attached to the radial border of the forearm in the manner illustrated in figure 2077. This illustration is copied from a photographic record, and it will be seen that the pedicle has been rotated so that its " seam " faces the dorsal aspect of the forearm. This rotation of the flap has never been found to interfere with its blood supply. Three weeks later the upper end is divided from the abdominal wall and about two-thirds of the flap is unrolled and cleared of excess fat. The forearm is carried across the forehead, dorsal surface backwards, where it is very readily fixed by strapping. This position causes no serious discomfort and it will readily be seen that it brings the flap into a position over the nasal defect eminently suitable for reconstruction of the nose. The stages

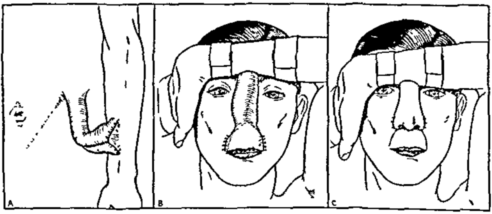

Fig 2077.—DRAWINGS ILLUSTRATING THE MANNER IN WHICH AN ABDOMINAL TUBED PEDICLE FLAP MAY BE TRANSFERRED VIA THE WRIST FOR RECONSTRUCTION OF THE UPPER LIP (B) AND AFTERWARDS FOR RECONSTRUCTION OF THE NOSE (C).

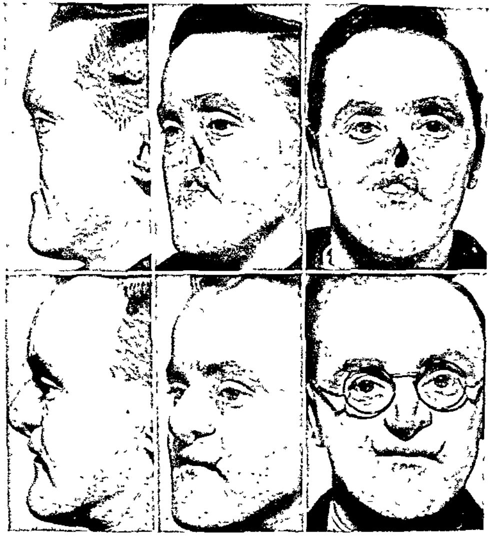

Fig 2078.—A CASE OF LUETIC DESTRUCTION OF THE NOSE AND UPPER LIP IN WHICH RECONSTRUCTION WAS CARRIED OUT IN THE MANNER SHOWN IN *Fig* 2077.

of in-turning and suturing are precisely similar to those already detailed.

In several cases such a flap has been employed to provide skin from its distal border for reconstruction of the upper lip before its more proximal part was employed in reconstructing the nose. Figure 2077 illustrates the manner in which this manœuvre is carried out. Figure 2078 is a record of a case in which this method was employed for reconstructing both lip and nose.

B. CORRECTIVE RHINOPLASTY

THE CROOKED NOSE

It is natural to expect that the most prominent feature of the facial contour will bear the brunt of the majority of facial injuries. Fractures of the bony bridge are extremely common in sports and in motoring accidents. While a nose deflected in moderate degree from the mesial plane may be insufficient to constitute serious disfigurement in a man, a similar degree of crookedness may be a very real handicap to a woman. Quite apart from cosmetic considerations, it must be remembered that the crooked nose is usually defective in function. It is true that clear nasal airways may be restored by submucous resection of the septum, but it must be obvious that this procedure is likely to give a less satisfactory result when a deflected bony framework is present than when obstruction is due entirely to deflection or deformity of the cartilaginous septum. Indeed, it would appear illogical to consider submucous resection the operation of choice in such cases. In some, correction of the bony displacement is in itself sufficient to clear the obstruction, for the septum comes over into correct position with the bone; in others, it would appear wise to aim at the maximum improvement obtainable by correction of the bony deformity, leaving any residual obstruction to be treated at a subsequent operation by submucous resection; while in still others again, it proves best to carry out a combined operation, the septal resection and the correction of the bony deformity being performed at the same sitting.

The general surgeon will take infinite pains to obtain good alignment in a fracture of a limb bone, yet the Nose and Throat specialist has, in the past, given very indifferent attention to fractures in his field of surgery. Malposition of nasal bones is frequently responsible for discomfort, and sometimes for actual pain of a neuralgic character.

RECENT FRACTURES

In fractures of the bony parts of the nose the fragments are almost invariably impacted, and simple external digital manipulation, the treatment so commonly considered sufficient, proves useless. Thorough disimpaction is the most important part of treatment. If tackled immediately after the accident, the classical method of introducing a blunt instrument of the elevator type into the nose and levering out the nasal bones should give satisfactory results. There is, however, frequently a doubt about the diagnosis, for swelling obliterates bony contours, crepitus is seldom elicited, and all manipulations are resisted on account of pain and tenderness. For these reasons early treatment, at a time when it should be relatively simple, is usually neglected altogether or is carried out in a very half-hearted manner.

For the efficient disimpaction and setting of a recent fracture of the nose, full anæsthesia is advisable. As a rule, this need be of only short duration, but if the patient is to be protected from inspiration or swallowing of blood and the surgeon saved from working in a blood-sprayed field, the anæsthetic should be administered by the intra-tracheal route. Evipan or even local anæsthesia may be employed where contra-indications to inhalation anæsthesia are present, provided efficient blood suction apparatus is available.

The operation should be carried out methodically and deliberately, and nothing should be allowed to interfere with the thoroughness of the work. No better instrument for manipulation of the fragments has been designed than the forceps originally devised by Walsham (*Lancet*, Aug. 29, 1891), and copied for me by Mayer and Phelps. These, right and left, with central or septal-setting forceps, are illustrated in use in figure 2079. The narrower blade is passed up the nose so that it comes to lie on the inner surface of the nasal bone, while the broader blade, shaped to correspond with the outer surface of the bone, is applied externally over the skin. This outer blade is usually covered by rubber tubing to avoid damage to the skin. The blades of these forceps do not meet, and there is therefore no crushing of the bone or its soft tissue coverings, yet a firm grip is obtained. The nasal bones are in turn rotated outwards to obtain thorough disimpaction. Simple external digital pressure now brings them into normal position and restores narrowness to the bony bridge. In most cases the septum has shared in the displacement, and it is always advisable to centralise this structure and at the same time correct any tendency to backward displacement of the bridge line.

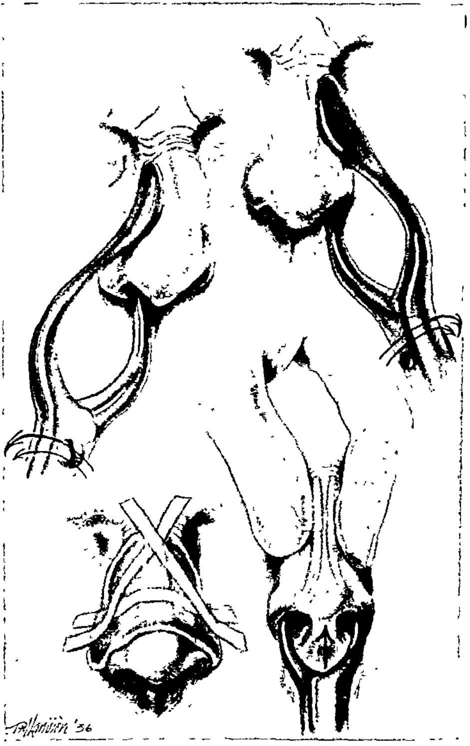

Fig. 2079.—Disimpaction and setting of a recent fracture of the nose. Walsham's forceps (right and left) and septum forceps are shown in use, and the method of splinting by Stent cast is indicated.

Splinting.

A simple method of maintaining the corrected position and preventing hæmatoma formation is as follows: a piece of sheet lead, cut to correct size and shape, is moulded to cover the front and sides of the nose. With this in position, a thin covering mould of Stent is made. This is cooled rapidly by trickling over it iced lotion from a dental chip syringe. The sheet lead, which has now served its purpose by holding the bones in position during the setting of the mould, is discarded. The mould is suitably trimmed and is strapped in position by adhesive strips passing from forehead to cheeks.

It is sound practice to pass a wick of tulle gras or of gauze soaked in liquid paraffin into each airway, not as a packing or splint but simply to prevent accumulation of blood clot which is liable to take several days to disperse. When the wicks are removed twenty-four hours later, nasal breathing is restored immediately and the patient is rendered much more comfortable. The mould may be removed at the same time or it may be retained for some days longer. It should be remembered, however, that its main function is to limit post-operative swelling and prevent re-displacement of fragments during the stage of recovery from the anæsthetic. Its retention for any length of time after it has fulfilled this function may be disadvantageous, for it is better to have the nose in full view rather than risk leaving it blindly fixed in what may prove to be a slightly incorrect position. Any tendency to re-deviation is very readily checked by digital pressure. Once disimpaction has been carried out completely—and the best criterion of this at the time of operation is that the nose can be readily pushed to the opposite side—there is very little tendency for the nose to become crooked again.

After-Care.

The majority of uncomplicated cases are kept under observation only over-night. Nostrils require gentle cleansing with hydrogen peroxide. They should then be dried and smeared with liquid paraffin. In some cases, undue swelling calls for longer after-care, and as the swelling subsides a careful watch must be maintained for any re-deviation. The patient is instructed to press in the nasal bones towards the mid-line with his fingers in order to keep the bony bridge narrow, and to press more on one side than the other should there appear to be any re-deviation during the setting process.

In cases in which the bones of the nose are extensively comminuted and when backward displacement is pronounced, the simple wire self-retaining intra-nasal splint devised by Watson Williams (*B.M.J.*,

Oct. 31, 1931), or the one introduced by A. B. K. Watkins (*B.M.J.*, Nov. 18, 1933), will be found useful. In some such cases it proves practicable to pass a silkworm-gut suture in mattress form, tied over small gauze rolls, from one side to the other, the needle finding its way between bone fragments.

In the most severe varieties of fracture, support may be obtained by extensions from a metal-cap splint fixed to the upper teeth. All such apparatus is uncomfortable to the patient. Many of the cases in which its use appears to be most clearly indicated fall into a category which calls for some secondary reconstruction of the bridge line by cartilage or other supporting graft at a later date. Although the indication to provide the best possible foundation on which to build is a clear one, careful judgment is required if over-long and futile efforts to support a badly comminuted bridge line by mechanical means are to be avoided.

Skiagrams of nasal fracture cases are seldom necessary, and unless taken by a radiologist with special experience are likely to fail to indicate the sites of fracture. They are reserved for the most part for doubtful cases in order to demonstrate to patients or parents the need for surgical interference. They are also useful as records in medico-legal cases.

It is wise in all severe nasal fracture cases to explain that the main aim of operative treatment is to correct crookedness as seen from in front, i.e., lateral deviation. It does aim, of course, at complete restoration to normal, but in some cases disturbance of the interrelation of cartilaginous and bony elements may produce some alteration in the bridge line contour as seen in profile. Another point worth mentioning is that a recently fractured nose may have been the subject of a previous fracture which has received no treatment. In such cases it is not to be expected that replacement of recently displaced fragments will reproduce a perfectly normal nose.

Probably the optimum time at which to operate on a nasal fracture is as soon as possible after the accident and before swelling has had time to appear. If this opportunity has been missed, it is as well to allow three or four days to elapse. By this time swelling has subsided to some extent, the deformity has become more obvious, and the patient is more convinced of the need for treatment.

The operation can be carried out successfully up to about three weeks after injury. After this time the bones have to a great extent "set" and manipulation by forceps is impossible or unsatisfactory.

OLD FRACTURES

When the nasal bones have become firmly set in malposition a much more complicated procedure is required to correct deformity.

Lateral vestibular incisions are made over the lower borders of the nasal bones. Through these the soft tissues are elevated on a subperiosteal plane. In order that rearrangement of the relation between skin and bone may be thorough, this undermining of soft tissues is not restricted to the regions of the nasal processes of the maxillæ but extends over the whole bridge and down towards the tip of the nose.

Lateral saw cuts are made (fig. 2080) which meet above, and the bony sides of the nose are " in-fractured " either by thumb pressure or by means of Walsham forceps.

In order to avoid unnecessary damage to the nasal mucous membrane, it is sound practice to pass the elevator upwards on the inner aspect of the bone and so separate the nasal muco-periosteum in the line of the proposed saw cut. The bony parts of the nose should be freely mobilised. The septum is manipulated into a central position, and the parts are moulded by the fingers and splinted in the manner already described for recent fractures.

In the most severe types of deformity it is essential to *excise* a wedge of bone on the longer side before the bridge can be persuaded to assume a central position.

When gross displacement or deformity of the septum is present, it is well to have the collaboration of a Nose and Throat specialist who will carry out a submucous resection of the septum first, saving the cartilage he removes for any building up of the bridge line which is required. The lateral vestibular incisions are not sutured but are left open to provide free drainage.

Careful post-operative observation of these cases is required. Digital manipulation is usually sufficient to prevent re-deviation and is preferable to the use of any form of external fixed apparatus.

THE HUMPED NOSE

The treatment of the bony hump follows closely that of the old fracture. Lateral vestibular incisions are made but these are extended forwards and then backwards on the sides of the membranous septum, which structure is transfixed (fig. 2080 [1]). Undermining is carried out as previously described. The bony hump is removed by saw, chisel, or the special instrument I have devised for this purpose illus-

trated in use in figure 2080 (2). The last mentioned has the advantage of cutting deeper as it passes downwards; chisels always tend to pass deeper as they are driven upwards and this is obviously undesirable.

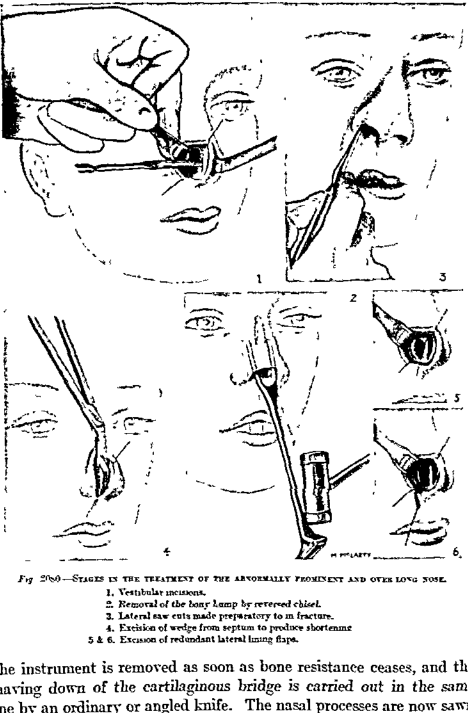

Fig 2080—STAGES IN THE TREATMENT OF THE ABNORMALLY PROMINENT AND OVER LONG NOSE.

1. Vestibular incisions.
2. *Removal of the bony hump by reversed chisel.*
3. Lateral saw cuts made preparatory to in fracture.
4. Excision of wedge from septum to produce shortening

5 & 6. Excision of redundant lateral lining flaps.

The instrument is removed as soon as bone resistance ceases, and the shaving down of the cartilaginous bridge is carried out in the same line by an ordinary or angled knife. The nasal processes are now sawn and in-fractured, and the bridge line is thus re-narrowed.

THE LONG NOSE WITH DROOPING OR WITH BULBOUS TIP

It is common to find one or both of these conditions associated with hump deformity.

Shortening of the nose and elevation of the tip are obtained by excising from the exposed lower border of the septum a triangle with its base forwards and its apex in the region of the nasal spine. The length of the base of this triangle is the index of shortening which may

Fig 2081.—AN EXAMPLE OF A RECENT NASAL FRACTURE TREATED BY DISIMPACTION AND SETTING.

be expected (fig. 2080 [4]). When the tip portion of the nose is tried in position it will be seen that there is an overlap of excess lining material on the lateral walls of the nose, and triangular areas (usually including the lower parts of the lateral [triangular] cartilages) must be removed to allow the wound edges to lie in apposition (fig. 2080 [6]). It is particularly dangerous to remove too much material in these situations, or an unpleasant " snarl " will be produced by the drag up of the nostril border.

The bulbous tip, almost invariably due to excessive bulk and

prominence of alar cartilages, is treated by careful exposure and removal of the upper halves or more of these cartilages on either side of the intercrural angles. Clearing of the cartilage is not easy, since both covering skin and lining are firmly adherent to it. Separation is facilitated by the injection of local anæsthetic or saline solution between the cartilage and its coverings. The septal incision is sutured, the stitches

Fig. 3962.—An example of an old fracture of the nose with pronounced deviation treated by submucous resection of the septum combined with surgical re-fracture and straightening

being passed in such a way as to draw the tip upwards and forwards to the desired extent. The lateral parts of the incisions are left open for drainage. Splinting is carried out as previously described, and wicks of tulle gras are passed into the airways.

It will be seen that various modifications or combinations of these procedures may be required for the infinite variety of nasal deformities encountered.

Figures 2081–2083 show examples of a recent fracture, an old fracture, and an over-long and over-prominent nose treated by the procedures described above.

Fig 2083 —AN ABNORMALLY PROMINENT AND OVER LONG NOSE TREATED BY THE TECHNIQUE SHOWN IN *Fig* 2080

THE DEPRESSED BRIDGE

Saddle Nose.

Mention has already been made of the treatment of those gross depressions of the nasal contour which follow luetic destruction of both mucosa and supporting structures. It may be repeated here, however, that the first essential in the treatment of these cases is the replacement of lost lining by Thiersch grafting. Only when the nose has been freed from the pyriform opening and brought forward as a whole is it justifiable to consider giving intrinsic support by cartilage implant. The less severe depressions of the bridge line are due to defective development, fracture, septal abscess, or excessive removal of cartilage in the surgical treatment of the deflected septum. In all these conditions the nasal contour can be satisfactorily restored by the implantation of a cartilage graft of suitable shape and size.

Where the tip of the nose is well supported, a single piece of cartilage

will achieve the desired result. Where tip support is deficient, the hinged graft (Gillies), consisting of a bridge piece and a columellar strut

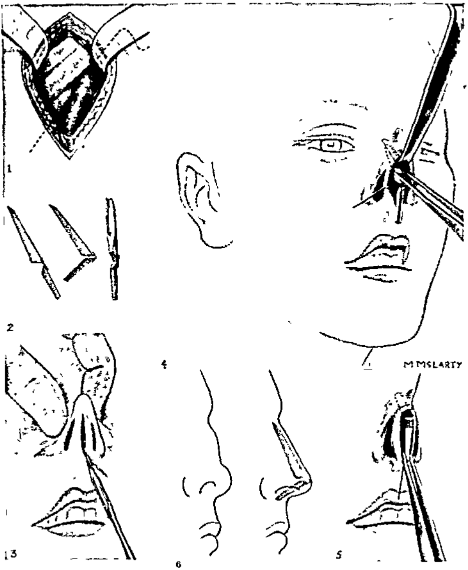

Fig 2084.—The technique of the treatment of the depressed nasal bridge by cartilage graft.

1. Exposure of costal cartilages from which the graft is usually obtained.
2. The graft prepared with perichondrial hinge. The posterior surface of the bridge piece is grooved to lie on the nasal bones above.

left attached to each other by a narrow strip of perichondrium, is required (fig. 2084). The bridge piece should be shaped to fit snugly on any remaining portion of the bony bridge, and is commonly grooved

on its posterior surface for this purpose; the columellar strut abuts against the anterior nasal spine at the base of the columella. In this way firm support and protrusion is given to the tip of the nose.

Fig. 2085.—Case record illustrating correction of the depressed nasal bridge line by cartilage graft.

In some cases, extensive undermining of skin extending well out to the sides of the nose is required; in others, a mere pocket for reception of the graft is sufficient. A graft which extends for the whole length of the nasal bridge gives a better appearance than one which runs only

left attached to each other by a narrow strip of perichondrium, is required (fig. 2084). The bridge piece should be shaped to fit snugly on any remaining portion of the bony bridge, and is commonly grooved

on its posterior surface for this purpose; the columellar strut abuts against the anterior nasal spine at the base of the columella. In this way firm support and protrusion is given to the tip of the nose.

Fig 2085.—Case record illustrating correction of the depressed nasal bridge line by cartilage graft.

In some cases, extensive undermining of skin extending well out to the sides of the nose is required; in others, a mere pocket for reception of the graft is sufficient. A graft which extends for the whole length of the nasal bridge gives a better appearance than one which runs only

part way up the nose. For this reason it has sometimes appeared wise to shave down an already high bony bridge at a preliminary operation before inserting the graft. Short of this, a graft may be notched on its posterior surface so that it abuts on the lower edge of the existing bony

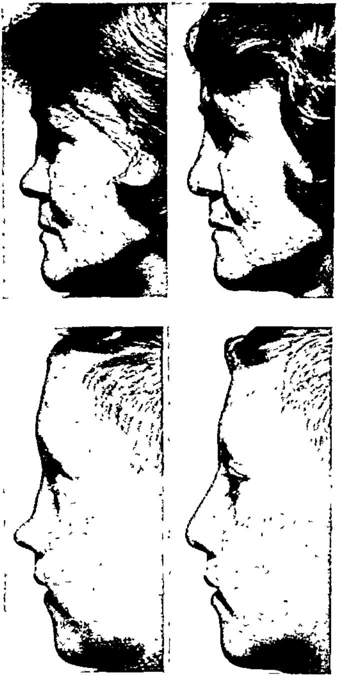

Fig. 2086.—OTHER EXAMPLES OF RESULTS OBTAINED BY NASAL CARTILAGE GRAFT.

bridge, or its upper end may be made to fit into a pocket in the same situation prepared by separating the muco-periosteum from the inner surface of the bone. The latter procedure is fraught with danger of opening into the nasal cavity, and so with risk of infection of the graft.

Nasal cartilage grafts may be inserted via: (1) an incision on the side of the membranous septum; (2) a vestibular incision where septum and lateral walls meet; (3) the columella–reflection route illustrated in figure 2087; or (4) the central columellar incision shown in figure 2084 [3].

Infection is rare; when it does occur, free drainage should be established immediately. If it fails to clear up speedily, it is wise to remove the graft completely rather than to wait for its slow extrusion or disintegration.

Figures 2085 and 2086 illustrate typical cases treated by cartilage grafts.

General Remarks.

Preliminary application of cocaine and adrenalin solution to the nasal mucosa makes for less bleeding and a clearer operation field.

The skin of the nose is very obliging, for it will usually shrink or stretch to accommodate itself to altered skeletal contours.

Although the incisions described above are the ones usually employed, there is no doubt that the clearest exposure for all work of this type is provided by reflection of the columella, as devised by Gillies (*Proc. Roy. Soc. Med.*, 1923) and as illustrated in figure 2087. This

approach entails, however, a small scar line at the junction of columella and lip, and in some cases such a scar would be very obvious and must be avoided. If the columella is to be reflected, it is well to make two fine scratches with a sharp needle across the proposed line of skin

section. These assist in accurate skin apposition at the end of the operation when the various changes which have been made in the parts make their correct interrelation a little obscure.

RHINOPHYMA

Little need be said about the treatment of this condition. In its incipient stages much may be done to check progress by carefully graduated X-ray or radium treatment. In its grosser forms, simple

Fig. 2088 —A CASE OF RHINOPHYMA TREATED BY SIMPLE SHAVING.

shaving away of the sebaceous material, thereby reducing the nose to normal proportions, gives excellent results. Such shaving leaves rosettes of epithelium derived from the sebaceous pits, and these rapidly spread to cover the whole nose with new and healthy skin. Figure 2088 shows a case treated in this manner and the result obtained three weeks after operation.

Care must be taken to avoid damage to cartilage or opening into the nose. Bleeding is apt to be alarming, but operation under local anæsthesia, and the free use of iced lotion and of carefully applied pressure-dressings do much to check this.

CHAPTER VII

Paraffinoma

Although the injection of paraffin wax is still advocated and practised by some surgeons of repute, the plastic surgeon who has had experience of the sequelæ of such treatment will find no words sufficiently strong to condemn it. Carefully employed, it represents a very simple means

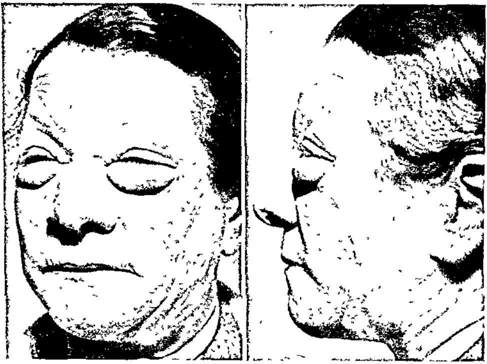

Fig 2089.—Gross lymphatic obstruction supervening many years after multiple injections of paraffin

of contour restoration in the nose, but it is never a safe method. I have never used it but I have spent many weary hours removing wax from nose, cheeks, chin and neck in cases where, frequently years after its insertion, it has become active, infiltrated the skin itself and, taking on the characters either of an infected foreign body or of a tumour, has worked its way towards the surface or even through the skin, or has gravitated into positions far removed from those of the original injections. Occasionally, it is found neatly encapsuled; its removal is

gratifying results. It is advisable that all aspects of such treatment should be fully discussed with the patient beforehand. The position and probable nature of scars, and the risks of hæmatoma formation, infection, and skin necrosis should be made perfectly clear, for it is obviously useless replacing one obsession by another. Future function of the remodelled breast should also be discussed. It is probable that little disturbance of function is produced, but it must be remembered that the heavy pendulous breast seldom contains much useful breast tissue. When a woman of child-bearing age seeks advice it is well to enquire about earlier function, about her intention to have further children and her desire to suckle them. I have no statistics on this point but Biesenberger of Vienna, who has probably devoted more thought and practice to this subject than any other single worker, claims to have many cases in which lactation and suckling have proceeded normally (even better than before) after his operations.

Careful examination should be carried out to exclude cases of carcinoma; patchy chronic mastitis need not be considered a contra-indication.

Time of Operation.

It is unwise to operate shortly after a pregnancy and before complete resolution has occurred. In order to avoid troublesome congestion and unnecessary hæmorrhage it is wise to choose a time between menstrual periods.

After trial of various procedures I have adopted as the operation of choice the one devised and fully described by Biesenberger whose book, giving a critical review of the whole subject, should be read by all surgeons embarking on this class of work.

The figures illustrating this section indicate better than words the *steps in the operation. All are based on those of Biesenberger, and only* slight modifications of the original technique have been introduced.

Although not essential and not practised by Biesenberger, some form of preliminary skin marking is distinctly helpful, for it will be seen that only slight asymmetry of position of the patient on the operating table is capable of leading the surgeon astray when he reaches the stage of placing the nipples in their new positions. Many such markings have been devised, but I have found those suggested by Claoué of Paris as reliable as any.

The patient lies comfortably on a couch with her hands on her hips and a line is drawn down the middle of the body, from the supra-sternal notch to umbilicus. A horizontal line is drawn at the upper level of the breasts and another one joining the submammary grooves. A third

horizontal line is drawn midway between the two former. Oblique lines are now drawn from the anterior axillary folds to meet at the intersection of vertical and lowest horizontal lines.

The ideal position for the new nipples lies, in my opinion, just outside and below the points of intersection of these oblique lines with the middle horizontal one. Dartigues places these points on a vertical line dropped from the junction of the outer and middle thirds of the

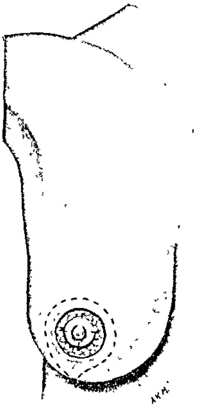

Fig 2090.—MAMMAPLASTY BIESENBERGER TECHNIQUE CIRCULAR INCISION IN AREOLAR SKIN AREOLA SUTURED AT FOUR POINTS TO BREAST. INCISION FOR REMOVAL OF PERI-AREOLAR SKIN STRIP INDICATED BY DOTTED LINE.

clavicle, four finger-breadths below the axillary fold. Such markings are valuable in that they indicate points symmetrically placed ; they should not be followed slavishly, the final new position for the nipples being chosen only when the breasts have been remodelled and covered by the skin flaps.

Figure 2090 shows the incision made to liberate the nipple. This incision is not necessarily carried around the areolar margin, for the areola in cases of hypertrophy and ptosis is usually greatly enlarged. An estimate is made of the size of areola which will prove suitable for

gratifying results. It is advisable that all aspects of s should be fully discussed with the patient beforehand and probable nature of scars, and the risks of hæmato infection, and skin necrosis should be made perfectly c obviously useless replacing one obsession by another. F of the remodelled breast should also be discussed. It is little disturbance of function is produced, but it must b that the heavy pendulous breast seldom contains much tissue. When a woman of child-bearing age seeks advi enquire about earlier function, about her intention to children and her desire to suckle them. I have no sta point but Biesenberger of Vienna, who has probably thought and practice to this subject than any other claims to have many cases in which lactation and suckli ceeded normally (even better than before) after his opera

Careful examination should be carried out to exclu carcinoma; patchy chronic mastitis need not be conside indication.

Time of Operation.

It is unwise to operate shortly after a pregnancy and plete resolution has occurred. In order to avoid troublesom and unnecessary hæmorrhage it is wise to choose a tim menstrual periods.

After trial of various procedures I have adopted as the o choice the one devised and fully described by Biesenberger giving a critical review of the whole subject, should be surgeons embarking on this class of work.

The figures illustrating this section indicate better than steps in the operation. All are based on those of Biesenberge slight modifications of the original technique have been m

Although not essential and not practised by Biesenberger r of preliminary skin marking is distinctly helpful, for it will only slight asymmetry of position of the patient on the op is capable of leading the surgeon astray when he reaches placing the nipples in their new positions. Many such m been devised, but I have found those suggested by Claou reliable as any.

The patient lies comfortably on a couch with her hands and a line is drawn down the middle of the body, from the su notch to umbilicus. A horizontal line is drawn at the upp the breasts and another one joining the submammary groove

pletely exposed. This undermining is carried out chiefly by blunt dissection with a gauze swab, scissors being used to divide any adhesions which do not separate easily. A considerable amount of fat should be left on the under-surface of the skin if necrosis is to be avoided. Hæmorrhage is comparatively slight and is checked up to this stage by large gauze swabs packed into the undermined areas.

The pectoralis major above and to the outside and the serratus magnus digitations below are exposed. The greater part of the outer

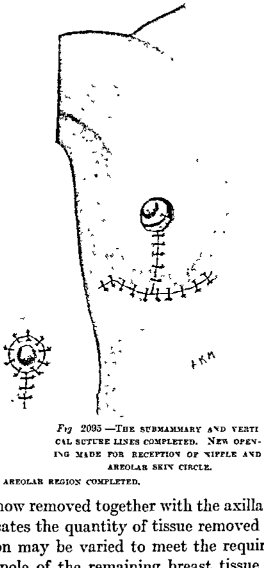

Fig 2095.—THE SUBMAMMARY AND VERTICAL SUTURE LINES COMPLETED. NEW OPENING MADE FOR RECEPTION OF NIPPLE AND AREOLAR SKIN CIRCLE.

Inset SUTURING IN AREOLAR REGION COMPLETED.

two quadrants of the breast are now removed together with the axillary prolongation. Figure 2092 indicates the quantity of tissue removed in an average case ; this proportion may be varied to meet the requirements of the case. The lower pole of the remaining breast tissue is now freed sufficiently to allow it to be rotated upwards and inwards. Trial is made of the position giving most æsthetic shape to the new breast, and when this position has been found sutures are inserted (as indicated in fig. 2093) to maintain the improved position. These catgut sutures should not take unduly large bites of breast tissue.

the reduced size of the breast. A further circular incision is now made about $\frac{3}{8}$-inch outside the former, and the ring of skin thus isolated is *stripped off the underlying breast tissue. Removal of the skin in this* manner prevents damage to the peri-areolar venous plexus, avoids troublesome hæmorrhage and gives less interference with the blood supply of the nipple than would knife dissection.

In cases where enlargement is considerable and ample skin is available, this second incision may be carried down to the submammary

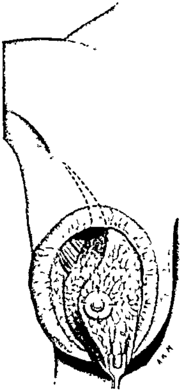

Fig 2092.—MAMMAPLASTY: BIESENBERGER TECHNIQUE. SKIN ENVELOPE SEPARATED FROM BREAST. OUTER QUADRANTS REMOVED BY "S SHAPED" INCISION.

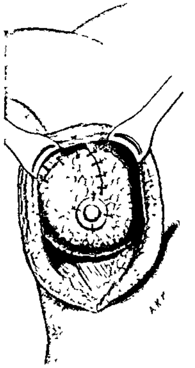

Fig 2093.—LOWER POLE OF REMAINING BREAST MATERIAL ROTATED AND FIXED TO BREAST TISSUE ABOVE AND TO PECTORAL FASCIA MARGINALLY. THIS MANŒUVRE RESTORES CONICAL FORM TO THE BREAST IN ITS NEW POSITION.

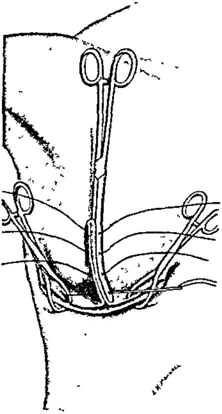
sulcus as in figure 2091. In other cases a vertical incision is made to the same point. Four fine sutures are inserted to fix the areolar skin to the breast tissue. This is an important point in technique, for the further manipulations are otherwise liable to pull on this skin and produce drag on the nipple itself.

The skin envelope covering the breast is now undermined in all directions, extensively above and to the outer side, and less extensively over the inner quadrants of the breast, until the breast is almost com-

pletely exposed. This undermining is carried out chiefly by blunt dissection with a gauze swab, scissors being used to divide any adhesions which do not separate easily. A considerable amount of fat should be left on the under-surface of the skin if necrosis is to be avoided. Hæmorrhage is comparatively slight and is checked up to this stage by large gauze swabs packed into the undermined areas.

The pectoralis major above and to the outside and the serratus magnus digitations below are exposed. The greater part of the outer



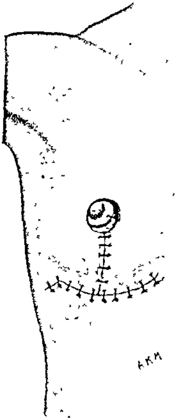


Fig 2094.—Trimming of the skin envelope to fit the reduced breast in its new position. Author's method of using a modified Doyen clamp in this procedure.

Fig 2095.—The submammary and vertical suture lines completed. New opening made for reception of nipple and areolar skin circle.

Inset Suturing in areolar region completed.

two quadrants of the breast are now removed together with the axillary prolongation. Figure 2092 indicates the quantity of tissue removed in an average case ; this proportion may be varied to meet the requirements of the case. The lower pole of the remaining breast tissue is now freed sufficiently to allow it to be rotated upwards and inwards. Trial is made of the position giving most æsthetic shape to the new breast, and when this position has been found sutures are inserted (as indicated in fig. 2093) to maintain the improved position. These catgut sutures should not take unduly large bites of breast tissue.

The breast should now occupy the desired position irrespective of skin covering, for no amount of shaping of the skin envelope will keep a badly remodelled breast in good shape.

The skin flap is now drawn over the breast and suitably trimmed. Figure 2094 indicates the device I have adopted for trial of the amount of skin excision required in the vertical direction. The skin is drawn through the modified Doyen stomach clamp until it fits snugly to the

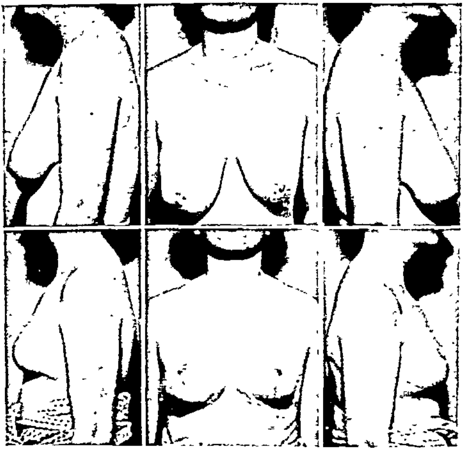

Fig. 2096.—Breast reduction and elevation in a case of asymmetrical enlargement and ptosis.

lower part of the circumference of the breast. Long straight needles armed with sutures are then passed through the holes in the blades of the clamp, the projecting skin is shaved off and the sutures are drawn through. The clamp is now removed and the sutures are tied.

A large fold of skin still remains in the region of the submammary sulcus. This is carefully trimmed away in such a manner as to keep the resulting suture line snugly placed under the breast in its new position. Every effort should be made to limit the inward prolongation of this

suture line. Its outer end should be kept well down or it will be liable to show when evening dress is worn.

Figure 2095 shows how a good finish may be obtained by carrying the outer extremity downwards a little and trimming the lower edge of a triangle at its outer end.

Further fine sutures are employed to complete the approximation

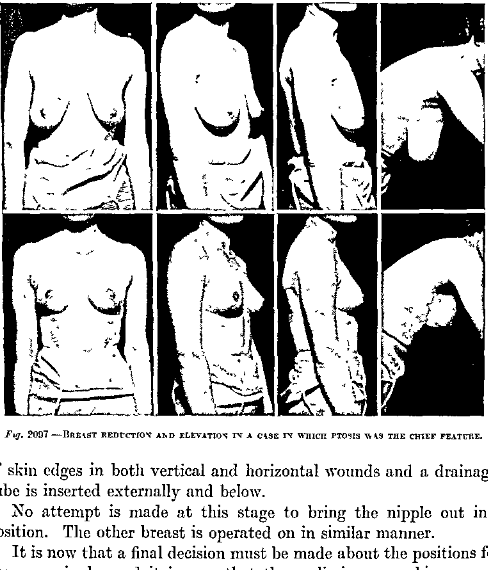

Fig. 2097.—Breast reduction and elevation in a case in which ptosis was the chief feature.

of skin edges in both vertical and horizontal wounds and a drainage-tube is inserted externally and below.

No attempt is made at this stage to bring the nipple out into position. The other breast is operated on in similar manner.

It is now that a final decision must be made about the positions for the new nipples and it is now that the preliminary markings prove helpful. Sites are chosen, not precisely at the centres of the eminences but a little below and outside these points. Various writers have suggested that, following the dictates of ancient sculpture, they should be placed above and outside these points, but experience indicates that the tendency is to place them too high rather than too low.

Circles of skin are removed similar in size to the areolar skin isolated

The breast should now occupy the desired position irrespective of skin covering, for no amount of shaping of the skin envelope will keep a badly remodelled breast in good shape.

The skin flap is now drawn over the breast and suitably trimmed. Figure 2094 indicates the device I have adopted for trial of the amount of skin excision required in the vertical direction. The skin is drawn through the modified Doyen stomach clamp until it fits snugly to the

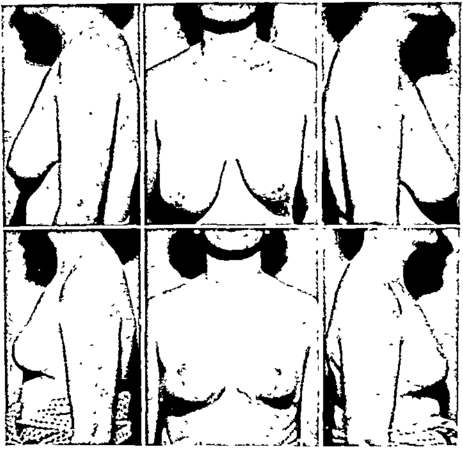

Fig 2096.—Breast reduction and elevation in a case of asymmetrical enlargement and ptosis.

lower part of the circumference of the breast. Long straight needles armed with sutures are then passed through the holes in the blades of the clamp, the projecting skin is shaved off and the sutures are drawn through. The clamp is now removed and the sutures are tied.

A large fold of skin still remains in the region of the submammary sulcus. This is carefully trimmed away in such a manner as to keep the resulting suture line snugly placed under the breast in its new position. Every effort should be made to limit the inward prolongation of this

suture line. Its outer end should be kept well down or it will be liable to show when evening dress is worn.

Figure 2095 shows how a good finish may be obtained by carrying the outer extremity downwards a little and trimming the lower edge of a triangle at its outer end.

Further fine sutures are employed to complete the approximation

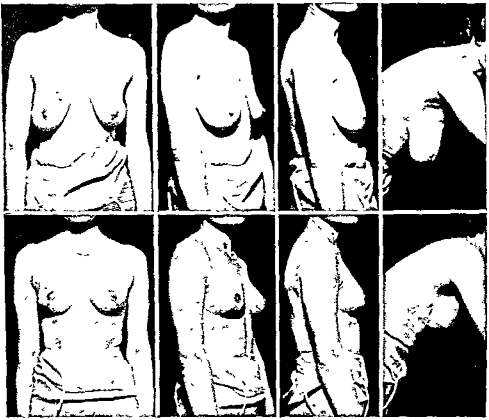

Fig. 2097.—BREAST REDUCTION AND ELEVATION IN A CASE IN WHICH PTOSIS WAS THE CHIEF FEATURE

of skin edges in both vertical and horizontal wounds and a drainage-tube is inserted externally and below.

No attempt is made at this stage to bring the nipple out into position. The other breast is operated on in similar manner.

It is now that a final decision must be made about the positions for the new nipples and it is now that the preliminary markings prove helpful. Sites are chosen, not precisely at the centres of the eminences but a little below and outside these points. Various writers have suggested that, following the dictates of ancient sculpture, they should be placed above and outside these points, but experience indicates that the tendency is to place them too high rather than too low.

Circles of skin are removed similar in size to the areolar skin isolated

by the initial incisions around the nipples. The nipples are brought out and marginal sutures are inserted, the preliminary fixation sutures being removed. Ideally the nipple should be found lying immediately under the new opening made for its reception, but occasionally some readjustment will be required; a plicating suture in the breast tissue, external

Fig. 2098.—Reduction and elevation in a case in which both enlargement and ptosis were severe. In this case secondary reduction of the lower part of the "new" breast was carried out some months after the first operation.

or internal to the nipple, is usually sufficient for this purpose. Nothing is more disappointing in results than the production of a nipple and areola which give the appearance of being dragged backwards and downwards through the skin opening. To avoid early drag of this kind—if the operation has been carried out perfectly there will be none—the skin surrounding the new opening may be "tacked" down to the breast tissue surrounding the nipple by an occasional mattress suture.

Tulle gras is applied over the nipples. The other suture lines are smeared with sterilised vaseline and covered by gauze. Copious cotton-wool dressings are used and a many-tailed bandage is applied to give snug pressure and support. A careful watch is kept for discolouration and threatened necrosis of the areolar skin, warm saline compresses being applied if necessary.

Drainage-tubes are removed in forty-eight hours. Sutures are removed gradually, some as early as the fifth post-operative day, others not until sound healing has occurred in from 7–10 days. Arm movements are restricted for about fourteen days.

For the first forty-eight hours or so patients show the ordinary after-effects of any prolonged operative procedure. After that time they seldom experience serious discomfort, and discharge from hospital is usually possible in fourteen days. The skin flap to the outer side of the vertical incision frequently becomes discoloured and occasionally shows superficial necrosis. In the early stages hot saline compresses are useful. When necrosis is established it is best to keep the parts dry.

Photographic records of cases operated on in this manner are presented in figures 2096 and 2097.

In most cases it is possible to achieve the desired reduction and elevation in a one-stage operation. In cases of gross enlargement the same operative procedure is adopted, but at a later date the vertical and submammary scar lines are reopened, excess of deep tissue is removed in wedge form, and the skin edges are suitably trimmed and re-sutured. Figure 2098 illustrates a case treated in this manner, the photographs showing the original, the intermediate and the final contour.

After operation patients are advised to wear a supporting brassière for some 4–6 weeks and to avoid any exercise involving active movements of the arms during that period.

Areas of induration and tenderness may persist for some weeks but these need cause no anxiety.

CHAPTER IX

Cleft Lip and Palate

There could be no more fascinating branch of reconstructive surgery than that which deals with the repair of congenital defects of the lip and palate; there is no work in which surgical judgment and meticulous atraumatic technique are more in demand; and there is no work in which collaboration with colleagues—pædiatrician, dental surgeon, and speech therapist—is more essential.

The vast literature of the subject is, in itself, evidence that many of the problems presented by these cases have not yet been solved, and this is not surprising when the infinite variation in type and the multiplicity of the factors involved are borne in mind. It would appear unwise to occupy valuable space by descriptions of classical operations or by arguments about the relative advantages of this or that procedure. Many years' experience of this class of work has led me to a selection of procedures which appears to offer the best possible chance of achieving the objects of treatment. It is, in this connection, a mistake to separate a lip cleft from a concomitant cleft of the alveolus and palate; on the treatment of one hangs the treatment of the other; only when the alveolus is intact can the two parts of the cleft be considered apart. I am in the habit of classifying cases in the manner suggested by R. P. Ritchie of St. Paul and have found this of great advantage:

CLASSIFICATION

Group I. Pre-alveolar Clefts.
Group II. Post-alveolar Clefts.
Group III. Alveolar Clefts.

Clefts falling into Groups I and II may present themselves in the same case; there may be a cleft of varying extent of the lip associated with a cleft of varying extent of the palate separated by an intact bridge of alveolar margin and a varying amount of un-cleft palatal tissue.

Clefts in Group III may be of almost endless variety. In unilateral complete clefts in this group it is usual to find the vomer attached, for a

varying distance, to the palatal process of the side away from the lip cleft. In bilateral complete clefts the vomer is central and unattached to either palatal process.

Pre-alveolar lip clefts may be unilateral or bilateral and may be complete (passing upwards to divide the nostril floor) or incomplete. Alveolar clefts may similarly be unilateral or bilateral, and complete or incomplete, varying from a mere notch of the alveolar margin on one side to the wide separation of the alveolar elements seen in its most severe form in those bilateral complete clefts of lip and palate in which the prolabium and premaxilla are situated far forwards and form a mere tubercle attached to the tip of the nose. Post-alveolar clefts vary from a mere split of the uvula to the long complete cleft reaching from uvula to alveolus.

Some rational classification of this kind is essential if reliable comparison is to be made in the results of operative treatment, for the type of cleft makes all the difference to the results which may be expected.

OBJECTS OF OPERATIVE TREATMENT

These may be summarised briefly as follows :

(1) To make the patient look well.
(2) To make the patient eat well.
(3) To make the patient speak well.

Of these the last is considered to be of greatest importance.

The patient can be made to look well by careful repair of the split tissues of the lip and nose. Repair in layers—skin, muscle, and mucosa —with meticulous attention to the correct placing of these tissues, with avoidance of waste of the available material and without unnecessary scarring, will achieve this object. The technical difficulties vary enormously, however, for while the repair of a pre-alveolar cleft is relatively simple, the arranging of tissues in a wide alveolar (Group III) cleft becomes a most difficult and complicated procedure. Indeed, in these latter cases, in which the bony parts are in abnormal position, it is impossible (and unwise) to make a lip and nostril which, at the time of operation, have a normal appearance. The main object of operation on such cases should be anatomical replacement of parts. It is surprising and gratifying to note that when this has been successfully achieved the lip and nostril show steady improvement in appearance as the action of the repaired lip succeeds in moulding the underlying skeletal deformity. It is for this reason that early operation (usually within the first 4–8 weeks) is advocated on lip clefts in this group.

ensures eversion of edges and prevents any unsightly notch formation in this region. All skin stitching is carried out with finest ophthalmic silkworm-gut mounted on atraumatic needles (plastasutes). Tension skin sutures have no place in lip repair work.

The first skin suture is placed at the skin-vermilion junction line and must be introduced with great care. In order to avoid irregularity of union in this region and to avoid the difficulty sometimes experienced in seeing this line at a later stage in the operation, I frequently mark it at the beginning of the operation with Bonney's Blue applied on a fine

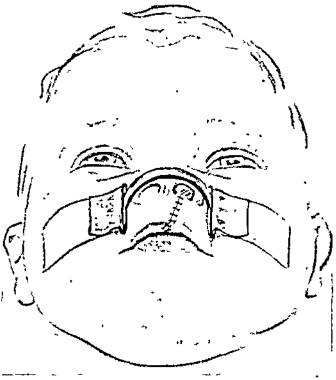

Fig 2100.—Logan's tension-bow applied.

mapping pen. Gentle tension on this first stitch brings the skin edges into correct apposition, and some five or six further sutures complete the skin closure.

All that now remains is to deal with the mucosal tags. A decision must be made as to how much can be safely trimmed away and whether imbrication or the formation of a flap from the outer side, to increase the prominence of the central part of the lip border, is advisable. Even in this limited region the formation of a flap of any material dimensions is to be avoided. It is wise to leave too much mucosa rather than too little; projections are very easy to remove later on if the cosmetic result is imperfect.

At the end of the operation a Logan's tension-bow is applied to prevent early drag on the suture line when the child cries. This device leaves the suture line exposed for periodical cleansing and for later removal of sutures (fig. 2100).

Sutures are removed as soon as possible. With the bow in position,

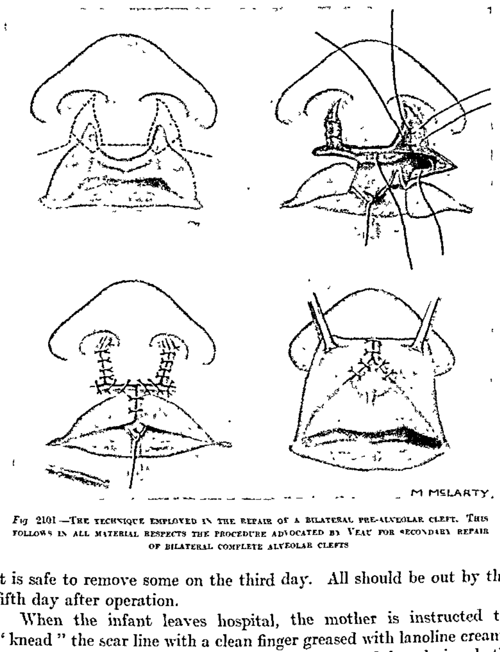

Fig 2101 — The technique employed in the repair of a bilateral pre-alveolar cleft. This follows in all material respects the procedure advocated by Veau for secondary repair of bilateral complete alveolar clefts

it is safe to remove some on the third day. All should be out by the fifth day after operation.

When the infant leaves hospital, the mother is instructed to "knead" the scar line with a clean finger greased with lanoline cream.

Bilateral pre-alveolar lip clefts may be treated by closing both clefts in this manner at the same operation. In the majority of such cases the central element is poorly developed and it is obvious that the prolabial skin should not be incorporated in the whole length of the lip.

It is in these cases that I break the self-imposed rule of avoiding the formation of flaps and repair the lip on the lines originally advocated by Veau as a secondary procedure for Group III bilateral clefts. Figure 2101 indicates clearly the technique employed.

Treatment in this group of cases is concerned almost entirely with appearance, but it should be remembered that an inferior lip repair may

Fig 2102.—Four examples of results obtained by the simple repair in layers of pre alveolar clefts. The final photograph of the adult patient is a studio portrait.

be responsible for incorrect production of labial sounds. Figure 2102 shows photographic records of clefts falling into this group and the results obtained by the simple form of repair described.

POST-ALVEOLAR CLEFTS. GROUP II

Clefts of the Palate.

In this group of cases treatment concerns itself almost entirely with providing the patient with a mechanism which will allow him to produce all the sounds necessary for normal speech.

The intact alveolar margin will, in the absence of gross and inexcusable trauma, prevent the occurrence of those appalling distortions of the dental arcade which are so frequently seen in Group III cases where closure of the palate cleft has been achieved by flaps drawn together under tension and with the formation of massive scar tissue. Masticatory disability should, therefore, never be seen in this group of cases.

How are the objects of operative treatment to be attained?

By the complete closure of the cleft, if possible, but more particularly by the provision of a mechanism by which the nose can be shut off from the mouth. No operation which fails in this latter respect can be considered successful. In the past, surgeons were satisfied if they could exhibit completely closed palate defects, and much time and ingenuity has been expended on ways and means of achieving such results. To-day the tongue depressor and inspection lamp should play no primary part in the examination of repaired palates. If the patient can speak clearly and naturally, and if he can snort and carry out those simple blowing tests which indicate efficient oro-nasal sphincteric control (Wardill), no visual examination is needed to decide whether the repair operation has been a successful one.

It is in the treatment of this group of cases, and into this group fall those Group III cases in which the lip cleft and the anterior part of the hard palate cleft have been repaired, that I have freely borrowed from the work or my contemporaries, gradually evolving a procedure which has for some years now been giving most gratifying speech results. Carried out before the child has made serious use of its defective speech mechanism, this operative technique succeeds, in a large proportion of cases, in giving normal speech without need for speech-training other than that provided by the child's natural speech trainers, its parents.

Space will not allow of both detailed written descriptions and illustrations and I have therefore considered it advisable to concentrate on the latter, reference to which should make the steps of the operation amply clear (figs. 2103–2105).

The essential points may be summarised as follows:

(1) *Pharyngoplasty.* (Wardill.)

(2) *Rotation flaps* from the hard palate. (Veau.)

(3) Extensive freeing of the soft palate tissues from the posterior borders of the palatal processes.
Free separation of nasal muco-periosteal flaps and approximation of these as far as possible throughout the cleft. (Veau.)
Employment of vomerine flap or flaps, when available, to assist in this nasal closure. (Veau.)

(4) *Hamular process fracture,* a procedure introduced many years ago by Billroth and re-introduced by Wardill and certain American workers in comparatively recent years.

(5) Free separation of the lateral pharyngeal wall from the internal pterygoid plate and its immediate neighbourhood. (Ernst and Axhausen.)

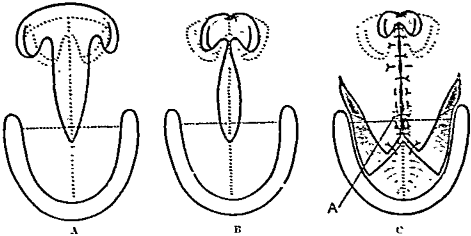

Fig. 2103.—Diagrams illustrating: (A) A post alveolar cleft of average proportions; (B) The effect of Wardill's pharyngoplasty; and (C) Repair of the cleft completed.

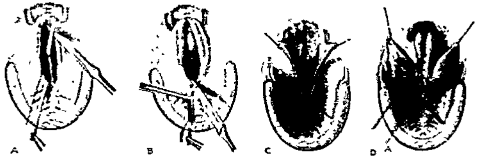

Fig. 2105.—Details of palate repair technique.

A. Paring the edges of the soft palate elements.

B. Completing the freshening at the anterior angle of the cleft.

C. Soft palate elements retracted to show pharyngoplasty suture line. Incisions marking out Veau flaps.

D. The hard palate flaps raised and freed. The nasal muco-periosteum has been elevated from the palatal processes, and some of the points of suture of the nasal layer are completed. The suture "A" is of silk worm-gut, and is later passed through the hard palate flaps and tied as shown in *Fig.* 2103 (c).

The reference after each is given not as indicating so much the original introducer as the surgeon in whose work I first observed this part of the technique.

Some general remarks on these procedures must be made.

In my opinion, the most important among the many infinitely important contributions which Veau has made to this subject is the introduction of rotation flaps to replace the older Langenbeck sliding or advancement flaps. These have enabled the surgeon to put into practice that very useful " V-Y " advancement principle, well known in other branches of plastic surgery, and so displace all available palatal material backwards to the situation where it is most needed. But this flap formation would be useless without the extensive freeing of parts on both upper and lower aspects of the bony processes which we also owe to the same worker. Veau seems inclined to attach less importance than I think should be given to the free separation of the soft tissues of the soft palate from the posterior borders of the bony processes, for without this, full posterior displacement of parts cannot be obtained. All this separation is carried out without dividing mucous membrane in the manner which formed an important part of the Langenbeck procedure.

It will be seen that when everything is ready for suture the palatal process has been completely " filleted " from its soft tissue coverings.

Veau's contributions to the repair of the palate cleft, however, begin before the main part of the cleft is tackled. The closure of any Group III cleft is facilitated in spectacular manner when the lip closure is combined with closure of the anterior part of the hard palate cleft in the manner advised by him and described later.

Trials of Veau's submucous wire suture (*suture musculaire*) left me dissatisfied. It achieved its object in preventing disunion of the soft palate suture line but was abandoned, in favour of hamular process fracture, as an unsurgical procedure producing fibrosis in its track which was likely to diminish the free mobility of the reconstructed soft palate.

Wardill demonstrated that the tensor palati muscle, the action of which fracture of the hamular process might be expected to disturb, is concerned more with deglutition than with speech. Its contraction draws the soft palate forwards, and from the speech point of view it is therefore better out of action. There is no doubt about the relaxation given by fracture of the hamular processes, and I have seen no disability produced by the procedure. It seems probable that the hamular processes become reunited in changed position and that the pull of the tensor palati thus adjusts itself to the changed position of parts. It

may even be true that in these circumstances this muscle changes its function and becomes an additional elevator of the palate, as suggested by Dorrance.

It was the uniformly good speech results produced by Wardill, in what was at the time a small series of cases, which led me to adopt his pharyngoplasty procedure as a routine measure.

In most cases, if not in all, the oro-nasal isthmus possesses abnormally large dimensions. As far as possible these were reduced by posterior displacement of the palatal tissues, but it seemed reasonable to add to this necessarily limited manœuvre anything which would bring the side walls inwards and the posterior wall forwards.

Wardill's pharyngoplasty, together with the lateral separation practised by Ernst and Axhausen, appears to be the best method available for the purpose, though it is realised that the spectacular immediate effects of these procedures do not persist in their full form. Even scar tissue in these regions must prove helpful, however, and infinitely superior to such procedures as paraffin injection or the implantation of fat, fascia, or cartilage grafts.

The illustrations show the stages of operation on a central cleft of limited length; it will readily be seen how these can be modified to suit clefts of different types.

When the vomer is available, the muco-periosteum from its sides supplies excellent flaps which assist in the nasal closure of the hard palate portion of the cleft. Sometimes the vomer is placed so high in the cleft that it is useful only as a point of fixation for the mattress sutures which draw the buccal flaps upwards into contact with the nasal flaps. Occasionally this object must be achieved by a suture drawn out through one of the nostrils and anchored by tying over a gauze roll. All these points in technique have been borrowed from Veau's work.

I do not divide the posterior palatine arteries as a routine, though Wardill holds that this is frequently necessary if complete freeing of the flaps is to be obtained; but occasionally, when the buccal flap is short and therefore in no danger of necrosis and when division of the artery promises to give greater freedom, I do not hesitate to ligature and divide it.

Wardill has recently introduced what he has described as a "four-flap method," and I have found this useful for closing wide clefts which extend far forwards. Short Veau flaps are made and extensively freed in the manner here described, and their arteries are divided if considered advisable. Anterior flaps, based on the anterior palatine

arteries, are then freed and rotated to meet in the middle line. It will be seen that this important modification of technique provides a means of avoiding or minimising the anterior defect which is left when long buccal flaps are cut and swung inwards and backwards. It also reduces the chances of flap necrosis in those cases in which complete freeing calls for division of the posterior palatine vessels.

ALVEOLAR CLEFTS. GROUP III

The widely separated elements of the gum margins in both unilateral and bilateral complete clefts of lip, alveolus and palate, give an opportunity not to be missed for dealing with the anterior part of the hard palate cleft when the lip repair is carried out. The Veau procedure in this region provides the only rational method of making a floor for the vestibule and a reasonable shape for the nostril. Further, it repairs the parts in correct anatomical manner, turning up into the nose vomerine muco-periosteum which belongs to the nose and which should not remain exposed in the roof of the mouth. It is impossible to achieve this with anything like the same satisfaction, if at all, later on when the lip is closed and the alveolar elements have approximated.

It is difficult to prepare illustrations indicating all points in this work because of the different planes concerned, but the subsequent figures show with reasonable clarity the several stages of the repair.

The operation on the palate is simple and need occupy very little time. The incision to free the vomerine flap is made first. It continues forwards and upwards behind the stump of the medial alveolar element on to the side of the septum immediately behind the columella (fig. 2106A). The flap is readily separated from the bone and is reflected upwards and outwards. Bleeding is checked by swab pressure.

The buccal flap on the lateral palatal element is now raised (fig. 2106B). This flap comes away from the bone readily, and it has never seemed necessary to make an incision along the outer border of the palate cleft. Hæmorrhage is again checked either by swab pressure or by pressing the flap firmly against the bone from which it has been raised.

I have found it of advantage at this point to forsake the strict Veau technique which completes the palatal part of the operation straight away.

Incisions are made in the lip and nostril. Those in the lip differ in no material way from those already described for pre-alveolar clefts. Mucosal tags are turned down from the margins of the cleft, but separation into layers is deferred until a later stage in order to diminish hæmorrhage. Incisions are made so as to outline a small triangular alar

base flap. The upper of these incisions is carried for a short distance upwards and backwards on the outer wall of the vestibule.

An incision is carried outwards in the gingival sulcus, and the soft parts forming the lip and the alar base are now carefully and freely

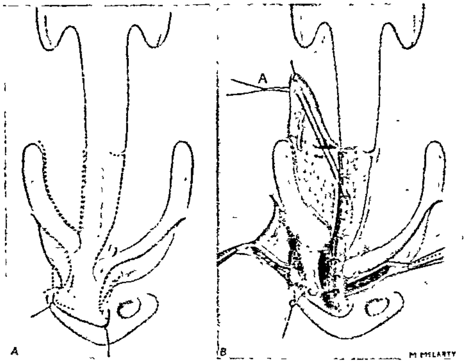

Fig. 2106.—Semi-diagrammatic drawings illustrating the technique employed at the first operation on a left complete unilateral alveolar cleft.

A. Incisions for freeing vomerine and hard palate flaps. The incisions in the lip region are similar to those shown in *Fig.* 2099. The base of the left ala has been freed for transposition later to the side of the septum.

B. The raising of the left lip element and the left alar base has exposed the ascending process of the maxilla. The vomerine flap has been sutured to the muco-periosteal flap obtained from the upper surface of the left palatal process and the side wall of the nose, and a floor for this part of the nose has thus been formed. The end of the suture "A" of silkworm gut, passed before the vomerine flap was sutured, has been carried through the hard palate flap and is ready to draw the latter over towards the right to cover over part of the raw surface exposed to the mouth.

C. The lip is repaired, as shown in *Fig.* 2099, by muco-muscular and skin sutures. The alar base flap is sutured into the triangular gap on the side of the septum and provides a good threshold for the nostril.

separated from the bone. This separation exposes clearly the ascending process of the maxilla (fig. 2106B). The muco-periosteum on the inner aspect of this process, i.e., on the lateral wall of the nasal fossa, is now separated. It comes away very readily and carries with it the inferior turbinate.

The separation is carried downwards on to the upper surface of the

palatal process, and a flap of nasal muco-periosteum is thus freed for the whole length of the hard palate cleft for later approximation to the free margin of the previously separated vomerine flap.

A silkworm-gut suture (A) is passed by a Reverdin needle through the vomerine flap in mattress form. The loop of this stitch is on the mucous surface, while its free ends emerge from its raw surface and are temporarily held out of the way in forceps. A number of catgut sutures are now

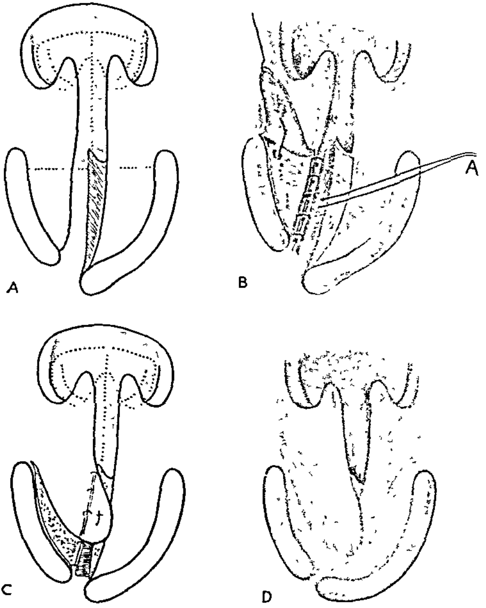

Fig 2107.—REPAIR OF LEFT UNILATERAL COMPLETE ALVEOLAR CLEFT.

A. Average cleft of this type

B. Vomerine and lateral nasal flaps sutured. Hard palate flap raised.

C. Hard palate flap superimposed on suture line and anchored by suture A.

D. Appearance of cleft of this type at time of palate repair 12 months after first operation. The appearance is similar in most respects to that presented by the post-alveolar cleft shown in *Fig.* 2103.

employed to approximate the edges of vomerine and lateral nasal flaps. These are passed by a Reverdin needle and are so arranged that their knots lie above. They are most readily passed from behind forwards and should be tied as they are introduced. The approximation of these flaps reconstructs the floor of the nose (fig. 2106B).

The ends of the vomerine flap suture are now passed through the buccal flap and tied. This brings the buccal flap over a considerable part of the suture line and reduces exposed raw surface to a minimum. The palate part of the operation is now complete (fig. 2107C).

The *remainder* of the operation follows closely that already described for closure of simpler lip clefts. The alar base flap is advanced to the side of the septum, where it is sewn into the triangular defect produced by the reflection of the vomerine flap. A few further points of suture

Fig. 2108.—Records showing results in lip and nostril regions obtained in complete unilateral alveolar clefts in two cases.

attach the upper margin of this flap to the anterior edge of the newly-constructed nasal floor. The position of this flap is shown in figure 2106C, but sutures have been omitted to avoid confusion.

The lip elements are approximated by muco-muscular catgut sutures and silkworm-gut skin approximation sutures. A Logan's bow is applied.

Figure 2108 shows photographic records of two cases treated in this manner.

Bilateral clefts are treated in precisely similar manner, but in two sittings. The lip result in such cases calls for secondary correction on the lines originally described by Veau and already mentioned in connection with those bilateral pre-alveolar clefts in which the prolabial element is under-developed.

Figures 2109–2112 show photographic records of cases of bilateral complete clefts in different stages of treatment.

It will be noted that no attempt is made in such bilateral cases to displace the premaxilla backwards by wedge excision from the vomer or by other means. The lateral lip elements are brought forward to it in its abnormally protruded position. This maintains a natural harmony

Fig. 2109.—A case of bilateral complete cleft of lip, alveolus and palate showing the result to be expected from repair of the lip in two stages. Secondary repair will give greater depth to the centre part of the lip, narrow the nostrils, and allow the prolabium and the tip of the nose to come forward.

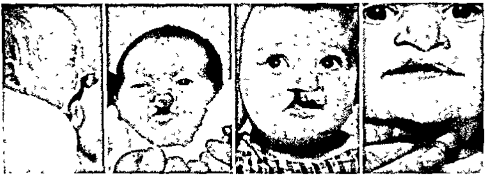

Fig. 2010.—A similar case showing the intermediate stage after closure of the left lip cleft.

Fig. 2111.—The result of repair of bilateral complete alveolar cleft. The lip and anterior part of the hard palate were reconstructed in two stages. The remainder of the palate cleft was repaired twelve months later. A secondary operation of the type illustrated in *Fig.* 2101 had been carried out a short time before the last photograph was taken.

Fig. 2112.—A case of bilateral complete alveolar cleft treated in similar manner to that shown in *Fig.* 2111.

in the relation of nose and lip, and avoids the very ugly, flat, retroposed lip which results from backward displacement of the premaxilla and closure of both lip clefts at one sitting. Gradual moulding of the premaxilla into better position is produced by the continual muscular contractions of the lip. In nearly all bilateral clefts of this group, however, further work is required later on, and in some cases the premaxilla is removed entirely and its place taken by a denture providing incisor teeth in correct alignment with the other upper teeth.

There are other varieties of cleft which have not been considered. Only one of these will be mentioned. The alveolus may be cleft on one side or on both, yet there may be no cleft of the palate proper. In the bilateral cleft of lip and alveolus of this type, protrusion of the premaxilla may be so marked as to call for lip repair in two stages, but in the majority repair can be effected as in pre-alveolar clefts.

GENERAL CONSIDERATIONS

Times to Operate.

There can be little argument against early closure of the lip cleft, and indeed few surgeons delay long in tackling this. It appears to me, however, unreasonable to fix any weight standard of fitness in this connection. Actual weight is of little importance, for children of widely different weights may be entirely fit subjects for operation. Nutritional progress is, in my opinion, the only sure criterion of fitness for operation, and I always leave it for my pædiatric colleagues to "say the word." On the other hand, it must be clearly understood that lip repair is never to be considered as urgency surgery. A child which can receive suitable attention can survive indefinitely with a widely open cleft lip. Every effort should be made to build up the infant's resistance before operation is attempted.

As already stated, it is my custom to operate on Group III lip clefts between the fourth and the eighth week. I am inclined to leave Group I cases, where there is no particular indication for early operation, until a little later, the time of operation being decided more by weather conditions than by age.

The use of mechanical appliances for temporarily filling the cleft and possibly facilitating feeding makes no appeal to me. Frail children from overcrowded homes are unsuitable for such treatment; an appliance intended to be a boon becomes a curse to patient and parent alike.

I operate on a cleft of the palate at or about one year of age. This time has been fixed because I feel that this is the earliest age at which

I can cope with the technical difficulties of the operation and the infant can survive the degree of surgical trauma which my manipulations involve. I am always anxious to have the repair completed before the child attempts to make serious use of his defective speech mechanism.

Theatre Lay-out.

I always operate on both lip and palate clefts from above the patient's head, which is thrown well back by placing a pillow under the shoulders. A low position of the operating table allows the surgeon to be seated and gives assistant and onlookers a good view of the operation field. The assistant stands on the right and manipulates the suction apparatus. The instrument Sister arranges her table close to the surgeon's right hand. Instruments are taken direct from, and returned to, this table by the surgeon, the Sister keeping them rinsed and in standardised order.

Illumination.

Any form of shadowless light is sufficient. When this is not available, headlights worn by surgeon and assistant have proved satisfactory.

Anæsthesia.

For the procedures described, intra-tracheal anæsthesia is essential, and I gladly acknowledge my indebtedness to Magill and his followers, whose developments have made this class of work possible.

Gag.

Experience of many kinds of gag left me dissatisfied in one way or another until Dott introduced the special Davis-pattern gag bearing his name. This, in a form only slightly modified to personal requirements, is made by A. Charles King & Co. It is used for all cleft palate cases. For the first operation on Group III cases, at which the anterior part of the palate cleft is treated at the same time as the lip repair, I employ the small size Lane's gag.

Instruments.

It is obvious that special instruments are required for the procedures here described, but no detailed list is given, since it must be equally obvious that different surgeons will find different instruments suitable for achieving the object of any particular manœuvre.

Team Work.

The surgeon who attempts cleft lip and palate surgery without the help of a well-organised team is courting disappointment. He may justifiably rank himself captain of this team but he should not consider himself as seriously more important than any one of its members. Intimate collaboration between surgeon and anæsthetist is of prime

importance. The anæsthetist makes the surgeon's work possible; the surgeon should see to it that he does nothing which will render the anæsthetist's work more difficult.

The theatre Sister, by failing to anticipate requirements, may be responsible for repeated delays which, in a relatively long and tiring operation, mount up and become an important factor to both patient and surgeon. *She should be "on her toes" the whole time.*

There is little room in or about an infant's mouth for two pairs of hands. The assistant does not get much of "a look in," but if he is quick and deft in his movements and, above all, if he has learnt the art —and it is an art—of using a suction end-piece to advantage, he makes a most important contribution to the operation.

Previous to, and after, the operation, the services of an expert pædiatrician are invaluable. Few surgeons can "spot," let alone treat, the disturbances peculiar to the small infant.

Only properly trained children's nurses know how to look after children, and I seldom persuade myself to undertake the treatment of a case unless expert nursing of this kind is available.

The later work on cleft lip and palate cases demands the services of an expert dental surgeon well versed in prosthetic work.

Records.

Good photographic records are invaluable, but very difficult to obtain unless the camera forms part of the operating theatre equipment as it does in Veau's service.

Personal notes of history, operation, and progress are essential if one's work is to indicate the relative value of different procedures and prove of use to others.

Operation notes should be written immediately after the operation, and graphic records should accompany these whenever possible. To help in standardising the latter I have had made a rubber stamp providing a dotted outline of the normal palate. The value of this is shown in some of the diagrams accompanying this section.

Warnings.

The infant's available airway is considerably diminished by closure of the palate cleft. A traction stitch should always be left in the tip of the tongue for use during the early stages of recovery from the anæsthetic.

If a palate suture line fails, never be in a hurry to re-operate. Discharge the child from hospital and wait for 3–6 months before attempting a secondary repair operation.

Be guarded in giving a prognosis when you are called upon to

operate on a palate which has already been operated on before. Scar tissue is unpleasant plastic material.

Never concentrate on closing small defects in the hard palate, forgetting, as so many surgeons do, the large defect behind the soft palate. Hard palate defects are readily filled by a dental plate. Remember that a long mobile soft palate in such a position as will provide oro-nasal sphincteric control should be the main object of all cleft palate surgery.

Summary.

The closure of unilateral and bilateral pre-alveolar clefts offers no serious difficulty.

The closure of complete unilateral clefts of lip, alveolus and palate is a difficult problem, and the repair of the lip cleft should always be combined with the repair of the anterior part of the hard palate cleft if an anatomically correct repair of the nostril floor is to be achieved.

Bilateral complete clefts of lip, alveolus and palate present still greater difficulties. Closure of one side of the lip cleft, together with the anterior part of the hard palate cleft of the same side, reduces the case to one of unilateral complete cleft, and this is repaired in similar manner as soon as the infant is fit for the further operation.

Successful repair in both these types reduces the palate problem to one similar to that presented by post-alveolar clefts.

Fig 2113.—This illustration is included to show the gross mutilation which may be produced by misguided secondary plastic work on the lip. Flaps have been taken from below the angles of the mouth and transferred to the upper lip, distorting the oral fissure yet contributing nothing of value to the upper lip.

Secondary Corrective Operations for Established Deformity in Cleft Lip and Palate Cases

Mention was made in the section on intra-buccal skin-grafting of the correction of the retroposed upper lip and nose (*see* fig. 2043). Reference has also been made to the Veau type of secondary correction of the deformity necessarily remaining after the closure of bilateral complete clefts in two stages.

Readers are referred for the discussion of these and other deformities about the lip and nose to an article by Gillies and Kilner published in *The Lancet* of December 24, 1932.

Figure 2113 is included to illustrate the mutilating effects produced by misguided secondary plastic work on an old bilateral complete cleft case.

CHAPTER X

Face-lifting Procedures

No work on plastic surgery would be complete without some reference to the so-called "face-lifting" procedures, for everyone practising this speciality is bound to encounter cases in which excessive loss of fat, due to illness or other causes, has produced a drooping, prematurely aged, and dejected appearance, that cannot be remedied by any non-operative cosmetic treatment. It is easy to argue that the operative treatment of such cases is a prostitution of the art of surgery; but there are many people to whom, in the keen competition of present-day existence, such stigmata mean much unnecessary suffering. In many instances earning capacity is directly related to appearance; actors and actresses, for instance, can seldom afford to look old. Men who have retired from public service, often after years spent in unfavourable climates, must supplement their pensions in order to give adequate support and education to their families, and have to seek work in the City, where first choice of employment is naturally given to those who still seem alert and vigorous. Shop assistants, too, find it difficult to obtain or retain employment if they show marked or unprepossessing signs of middle age. There are also other than economic reasons for these operations. There are, for example, numbers of unfortunate people who, though not in any way given to dissipation, present a dissipated appearance. One has only to listen to the pathetic stories told by people in such circumstances to realise how their lives are rendered miserable by their disfigurement, and to feel amply justified in carrying out the comparatively simple and certainly not dangerous procedures which will restore them their self-confidence and peace of mind.

There are other cases where the procedures are useful. Acne scarring of the face, X-ray effects sufficient to cause atrophy of the skin and wrinkling without any true dermatitis or necrosis, and depressed scars unsuitable for individual excision, may be greatly improved by stretching the skin in the same manner.

The usual excisions for this work are made at the junction of hairy scalp and non-hairy face skin, and it is from the latter that the necessary excisions are made. Numerous varieties of excisions from hairy scalp

apparently devised so that scars can be more completely hidden, have been described. In my opinion these have no place in the work. They result in the gradual pulling back of the hair-line and the sacrifice of hairy skin, and do not remove skin in the non-hairy regions where lack of tone and stretching is responsible for drooping and wrinkling.

Most operations of this kind are carried out under local anæsthesia. The injection of the solution obliterates normal contour. It is wise, therefore, to indicate the line of incision carefully by pen and ink before injecting.

It is dangerous to depict excision areas for this work, for no case should be commenced by outlining such areas. The main points of upward and backward pull are in the temporal and post-mastoid regions. Incisions are made here precisely in the hair-line. They are joined by an incision which passes down in the skin fold in front of the ear, around the attachment of the lobule, and upwards and backwards in the retro-auricular furrow (fig. 2114). The lower edge of this incision is raised, and undermining of the skin of the cheek and neck is carried out on a superficial plane for a greater or less extent according to the degree of facial or cervical prolapse. It is sound advice to suggest that this undermining should be accomplished by scraping, as it were, the deep surface of the skin. If this is done, bleeding is not severe and there will be no danger of damaging underlying nerves or other structures.

The skin flap thus raised is drawn upwards and backwards by tissue hooks or tenaculum forceps placed at its temporal and mastoid points, and trial is made of traction in different directions to find which gives the best results on the cheek and neck. Held in this position by an assistant, the flap is incised where it lies over the upper edge of the original incision at the two areas of main pull. A single suture of strong but fine silkworm-gut is inserted at each of these points. Once these are fixed it is easy to trim away the remaining redundant skin and complete the suture of the wounds.

Pull on the ear, and more particularly on the lobule, is to be stringently avoided. In most cases it will be found necessary to remove only a narrow strip of skin from that part of the flap which overlaps the incision in its course around the ear attachments.

The stitches employed are of the interrupted variety throughout for this allows of the early removal of those on which there is no tension Occasionally, in cases in which the cheek tissues are particularly heavy and pendulous, a long mattress suture of silkworm-gut is employed to take all strain from, and allow earlier removal of, the skin approximation sutures. This is passed through the scalp skin a short distance

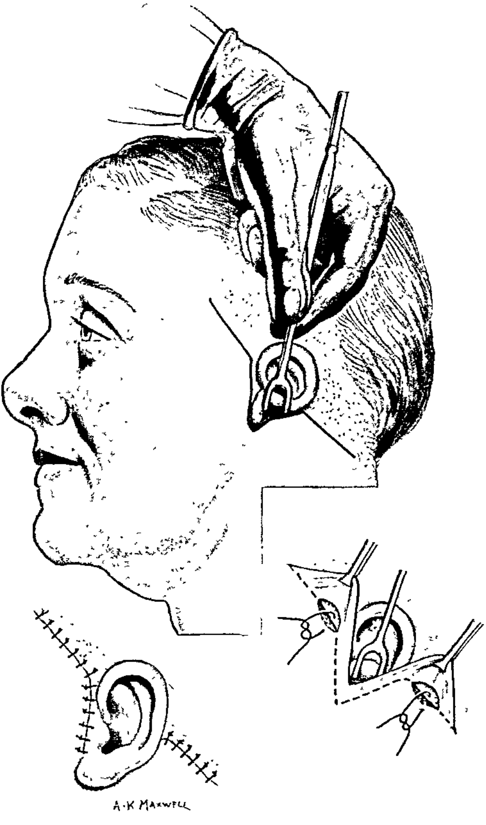

Fig. 2114.—THE TECHNIQUE OF FACE LIFTING.

above the incision in the temporal region, picks up the deep tissues of the cheek at the limit of skin undermining, and returns to emerge through the scalp skin adjacent to its point of entry where it is tied over a small button. This suture is retained until the other sutures have been removed.

Ordinarily no drainage need be provided but hæmatoma formation must be avoided at all costs. Definite bleeding points must be ligatured, but buried catgut in so superficial a position is liable to be troublesome, and as little as possible should be used. When oozing has been persistent during the operation it is wiser to insert drains of twisted silkworm-gut in the temporal and post-mastoid regions than to run the risk of having to open the wound later to evacuate blood clot. In most cases, carefully graduated pressure-dressings over the undermined areas, held firmly by crêpe bandages, are sufficient. Ice-bags and iced hammamelis lotion compresses are used freely to counteract congestion and bruising.

In some cases where there is much fulness of skin about the outer canthus of the eye, or where extensive upward pull produces some danger of dragging up the outer angle of the palpebral fissure or the outer end of the eyebrow, it is found useful to excise a small horizontal triangle of skin from the anterior edge of the wound at the level of the eye. This distributes the redundant skin more uniformly and leaves a scar which is difficult to trace after a very short time.

Working at the margin of the hairy scalp with hair exposed throughout the operation is unpleasant. Quite apart from the risk of infection the hair gets very much in the way when sutures are being inserted and tied. If a patient is not anxious to make an early reappearance in public, limited shaving makes the operation safer from the point of view of asepsis and is much easier. The hair-line should be clearly indicated either by preliminary marking or by leaving the actual marginal hairs cut short but not shaved. Where this is impracticable, it has been found helpful to "mat" the hairs together and smooth them away from the proposed incision line by a sterilised fixative cream made up from tragacanth.

Pre-auricular sutures are removed in three days lest they leave transverse markings. Cotton wool soaked in collodion is applied over the scar line in order to prevent early stretching or damage by the movements of the patient. Such protective dressing is particularly called for around the attachment of the ear lobule. Other sutures are removed, some in five and some in seven days.

Double Chin.

It is seldom justifiable to make a scar in the submental region for the removal of excessive fat deposit. Very occasionally, when a deep groove, in every way as disfiguring as a scar, is present, a curved transverse incision may be employed for this purpose. The vertical scar, still occasionally seen, is usually keloidal, contracted, and extremely disfiguring.

Eyelid Wrinkles : Upper Eyelids.

Skin folds in the upper eyelids, giving a heavy, sleepy appearance, are readily removed by simple crescentic excisions (fig. 2115). Local anæsthesia is employed, and care is taken to place the injections subcutaneously and to avoid injecting more solution than is necessary. The instillation of a few drops of butyn 2 per cent into the eye at intervals during the half-hour preceding the operation prevents involuntary movements and removes a great deal of the apprehension otherwise present. The excision is planned so that the resulting scar line

Fig. 2115.—Operation for excessive fulness of skin in upper eyelids.

will fall in the natural fold of the eyelid in the open position of the eye. It is sound practice to mark out the line of this fold before injecting, and to indicate the breadth of the strip which, by trial beforehand, it has been shown can be spared without distorting the eyelid margin. The skin crescent may be outlined by a scalpel and dissected away by scissors ; it may be pinched up in hæmostatic forceps and crushed in such a way as to make it stand up as a ridge which can then be readily removed by scissors ; or it may be both outlined and removed by sharp-pointed scissors. The first-mentioned method of removal is inclined to give incisions which go too deep and cause unnecessary bleeding ; the second is very simple but not sufficiently precise ; the third is probably the best method of the three.

Slight undermining of the edges of the wound, although not always essential, allows of more perfect skin apposition.

The subcuticular suture, always employed in this situation, prevents inversion of the edges and provides for easy removal. No knots are tied, and the suture ends are left long enough to be fixed down to the skin by small pieces of strapping. The sutures are removed in 48–72

hours. Iced Pond's Extract compresses are applied immediately after the operation and are renewed at frequent intervals to limit bruising and swelling.

The scar lines left by this operation are invariably good and, when correctly placed, become very difficult to find within a few weeks of the operation.

Lower Eyelids.

The removal of redundant skin from the lower eyelids is carried out in much the same manner as in the case of the upper eyelids, but here a much more careful judgment is required of the amount of skin which can be spared without producing eversion of the lid margin. This is particularly important in the "senile" atonic eyelid, where the removal of even a narrow strip of skin may drag the eyelid margin away from

FIG 2116.—OPERATION FOR EXCESSIVE FULNESS OF SKIN IN LOWER EYELIDS.

its normal contact with the globe and, apart altogether from appearance, may lead to troublesome epiphora.

The upper incision is placed very close to the eyelash margin; in this situation the resultant scar is well hidden. In order to prevent downward drag, where much skin appears to be redundant, and in order to tighten up generally the skin of the whole eyelid, it is usual to extend the excision downwards at its outer end, as in figure 2116. The skin below is undermined for a short distance. Closure of the lateral extension of the wound brings the edges of the remainder into juxtaposition, and here again a subcuticular suture is employed.

Eyelid Pouches.

There is a type of deformity which occurs in both upper and lower eyelids, but much more commonly in the latter, which no amount of skin removal will correct. It appears to be due to herniation of orbital fat into the tissues of the eyelid and takes the form of pouches. These disfiguring pouches may present themselves in quite young subjects.

Bourget and Passot of Paris have advised removal of such fatty herniæ through incisions in the conjunctival fornices, but such a procedure, fraught as it must be with danger of infection although producing no external scar, has never appeared to me to be justifiable. It would seem safer to gain access to such fatty collections by reflection

of skin and separation of the fibres of the orbicularis palpebrarum muscle. They are not difficult to isolate and are treated like herniæ elsewhere. The sac is cleared and opened and its edges are picked up in delicate forceps. The fatty contents are freed, clamped, ligatured, and removed. The sac is closed by catgut sutures and the muscle-fibres allowed to fall back into natural position.

It is usual to combine some skin removal with this procedure. Post-operative bruising and swelling are more severe than after skin removal alone, but the final result is usually very gratifying.

Forehead Wrinkles.

There is occasionally a clear indication for carrying out an excision from the forehead region—when frown lines or forehead wrinkles are disfiguring. In such cases the incision is again made at the junction of hairy and non-hairy skin. The lower edge of the wound is undermined to a suitable extent and the skin flap thus raised is reduced and adjusted in the manner described for temporal face-lifting. In order to eradicate forehead lines and lift drooping eyebrows, considerable undermining is required and bruising is usually severe.

Elliptical excisions placed laterally in the frontal hair-line are usually sufficient, if combined with extensive undermining, to eradicate vertical frown lines in the glabellar region. It seldom seems justifiable to produce a vertical scar in the latter region for the removal of redundant skin. The remarks already made in reference to submental incisions apply to this region also.

Operations for lengthening or shortening the palpebral fissure are relatively simple, but are considered quite unjustifiable except in the presence of real congenital deformity.

PART XX
OBSTETRIC SURGERY

by
ALECK W. BOURNE

OBSTETRIC SURGERY

Introduction

The greater our experience of the practice of surgery, the more we feel that the emphasis laid on difficulty moves from the execution of technique to the formation of a correct judgment on which our technique may be based. During the earlier years of practice it is probable that our chief interest lay in the mastery of the actual steps of technique, and in the acquisition of deftness and speed. We were fascinated by the anatomical scope offered by surgery and our interest was almost proportionate to the difficulty and danger of the more serious and radical operations. There was a thrill in seeking some deep and secret recess of the body. It was an adventure which tested courage, knowledge, skill and decision. The subsequent days or weeks maintained the interest as we watched, sometimes with alternating doubt and hope, the clean and quick recovery to convalescence. The patient presented an exercise in technique rather than a problem of pathology and treatment. The operation on the lesion was the chief interest, not the consideration of the best course which would ensure the recovery of the whole individual man.

When, therefore, we remember the fascination of our early experience in surgery it is not surprising that there was a temptation to exalt technique, and some of the more mechanically minded amongst us never progress beyond this stage.

But as time passed, the actual operation, while always able to hold our whole attention, gradually began to take second place in the general survey and treatment of any given patient. The growing familiarity with and facility of an oft-repeated performance allowed the much greater problem of judgment and pre-operative decision to assume the chief part. One of the characteristics of the mature and experienced surgeon is the greater importance which he attaches to the preparatory consideration of the diagnosis, and to the choice of the particular operation which will be most calculated to ensure the maximum benefit to the patient, both immediately and in the more distant future.

Whereas almost any man who has had a few years' practice at the actual handicraft of surgery can develop a safe and dexterous technique, it may require much more time before he has acquired a sound opinion

OBSTETRIC SURGERY

Introduction

The greater our experience of the practice of surgery, the more we feel that the emphasis laid on difficulty moves from the execution of technique to the formation of a correct judgment on which our technique may be based. During the earlier years of practice it is probable that our chief interest lay in the mastery of the actual steps of technique, and in the acquisition of deftness and speed. We were fascinated by the anatomical scope offered by surgery and our interest was almost proportionate to the difficulty and danger of the more serious and radical operations. There was a thrill in seeking some deep and secret recess of the body. It was an adventure which tested courage, knowledge, skill and decision. The subsequent days or weeks maintained the interest as we watched, sometimes with alternating doubt and hope, the clean and quick recovery to convalescence. The patient presented an exercise in technique rather than a problem of pathology and treatment. The operation on the lesion was the chief interest, not the consideration of the best course which would ensure the recovery of the whole individual man.

When, therefore, we remember the fascination of our early experience in surgery it is not surprising that there was a temptation to exalt technique, and some of the more mechanically minded amongst us never progress beyond this stage.

But as time passed, the actual operation, while always able to hold our whole attention, gradually began to take second place in the general survey and treatment of any given patient. The growing familiarity with and facility of an oft-repeated performance allowed the much greater problem of judgment and pre-operative decision to assume the chief part. One of the characteristics of the mature and experienced surgeon is the greater importance which he attaches to the preparatory consideration of the diagnosis, and to the choice of the particular operation which will be most calculated to ensure the maximum benefit to the patient, both immediately and in the more distant future.

Whereas almost any man who has had a few years' practice at the actual handicraft of surgery can develop a safe and dexterous technique, it may require much more time before he has acquired a sound opinion

based upon a true clinical insight. In no branch of surgery are these remarks better illustrated than in obstetrics. The actual performance of the operations is not, as a rule, difficult, though occasionally they may tax all our skill, but the decision of the right course of action in an obscure case must be a matter for the most careful thought. *An obstetric instinct and years of contact with patients in labour are* necessary before confidence arrives. Knowledge of *what* to do rather than knowledge of *how* to do it is a relatively late growth in the development of our surgical capacity, but it is of the greatest importance to our patients.

The majority of maternal deaths follow some form of interference, and we can say further that a substantial proportion of these are caused not so much by the technique employed, as by the unsound decision which preceded and prompted the operation. There are many reasons given to account for these errors of judgment; in many cases it is no more than a matter of saving time during a busy day's work which is the incentive to apply forceps. But one of the main underlying reasons is a fault in the teaching which tends to emphasise its surgical aspect and its mechanical problems, with the result that the attitude of mind is formed which finds a need for "helpful" interference at too early a stage in labour. Our teaching does not sufficiently stress the importance of *prognosis* during labour, which can only be based *upon a knowledge of function. Our emphasis is not placed upon the* physiology of uterine contraction and cervical dilatation but upon the mechanics of labour. The idea of disproportion of size of the head and pelvis dominates obstetric teaching. It is purely a mechanical conception, it is taught as such, and is therefore regarded as amenable only to a mechanical treatment. We do not teach sufficiently the phenomenon of the uterine contraction, the stimulating and inhibitory forces at work, the adaptability of the fœtal head, the existence of pelvic reserve, and lastly but not least the temperamental constitution of the individual woman. A better knowledge of these clinical details, and therefore of the prognosis of labour, would correct the widespread tendency to interfere during labour, and therefore reduce the rate of injury, hæmorrhage and sepsis.

It is the common *experience of obstetricians that the majority of* disasters follow manipulative interference rather than abstention therefrom. In other words we may say, "when in doubt, do nothing." Only the clearest indications for action should prompt an obstetric operation, and therefore my account of obstetric surgery will be concerned with discussion of methods and choice of procedure rather than with the steps of actual technique.

CHAPTER I

Induction of Labour

The artificial termination of pregnancy after viability is termed induction of labour. It is usually carried out before full term, in which case it is, strictly speaking, induction of premature labour, but sometimes it may be indicated after the calculated date of full term to prevent further post-maturity. The operation was first performed in 1756 by Denman in a case of contracted pelvis as an alternative to Cæsarean section and craniotomy, which carried, in those days, such a high mortality.

During recent years the operation has been practised very widely, not only for contracted pelvis but for many other indications which are thought to endanger the health or life of either mother or child. The comparative ease and safety of the methods in use are partly responsible for the prevalence of these operations, but it is doubtful if, in many cases, they are actually necessary. The widespread adoption of ante-natal care has provided opportunities for the discovery of many conditions in many patients as possible indications for induction of labour, but not all these conditions are real indications, and there is a tendency to see danger in allowing pregnancy to continue where none really exists. Particularly is this the case in so-called "disproportion", and in certain diseases associated with pregnancy.

It may be true that induction of labour is a comparatively safe operation, but it is by no means without risk. Professor Browne (*Lancet*, 1932, ii, 1) states that of the maternal deaths among booked cases at several obstetric hospitals one in twenty followed induction of labour, while at Queen Charlotte's Hospital the operation adds 0·23 per cent to the average death-rate of labour. It might be urged that if these patients had not been treated by induction of labour the death-rate from the condition for which induction was employed would have been greater, but as experience has shown us how many times it is performed for no adequate reason, it is probable that, in the aggregate, the results would be better if the operation were done with more circumspection.

This is not the occasion for criticising ante-natal care, but it is undeniable that it has been associated with a continued rise in maternal mortality and also with a wider interference with pregnancy, of which induction of labour is one feature. We will not fall into the simple syllogistic error of suggesting that the above reasoning shows that increasing prevalence of induction is a cause of an increasing maternal death-rate, but what may fairly be examined is the proposition that interference in pregnancy, including induction and Cæsarean section, does play a part in the rising maternal mortality. There are some well-defined conditions for which induction is a necessary form of treatment both for mother and child; there are others in which it is a matter of opinion. In the latter group fall the large number of cases of so-called disproportion. How far it is a good or necessary measure for this condition I shall discuss more fully in a later section. If the operation were entirely harmless the discussion would lose most of its point, but it has a definite risk not only of morbidity but of death. For example, during 1933, 256 cases of puerperal sepsis of all forms were admitted to the Isolation Block of Queen Charlotte's Hospital; of these 12 (4·7 per cent) cases had had labour induced by mechanical methods, and 5 patients (42 per cent) died. While other ætiological factors such as instrumental delivery were associated, and may have played a part, there are at least 3 of the 12 of whom no other factor is recorded. Further evidence of actual mortality has been supplied by Browne, who found that of 173 deaths collected from 8 maternity hospitals during the years 1927 to 1930 there were 8 due directly or indirectly to induction of labour. In these hospitals, which were high-grade, well-run institutions, about 1 in every 20 deaths followed mechanical induction. If these disasters followed a necessary operation for conditions which, if untreated by this method, carried a higher risk, there could be little criticism, but it is certain that large numbers of cases of "disproportion" had premature labour induced entirely unnecessarily.

There are other criticisms that can be laid against local interference as a method of induction of labour. The time elapsing between the introduction of the bougie and the onset of labour may be prolonged to such an extent that anxiety is felt lest the further retention of the bougie *in utero* may cause sepsis, while the tedium and uncertainty of the patient is sufficient to make her unwilling ever to have the operation repeated. It is true that the labour pains usually begin within three days, but quite commonly the delay may be as much as five days or more. If the insertion of a foreign body into the uterus or rupture of

the membranes fails after a reasonable time, the local condition is unfavourable for the operation of Cæsarean section, in view of the probability of infection. This difficulty may become serious in certain cases of disproportion where failure of induction of premature labour subsequently involves Cæsarean section.

But, having stated some serious disadvantages of this operation, it must be admitted that where it is truly indicated it may be a life-saving measure, both for the mother and the child. The conspicuous example of success is the treatment of toxæmia, whereby eclampsia and renal damage may be prevented.

During recent years increasing attention has been devoted to so-called "medical" induction which does not involve the mother in any risk. As we shall show later, it is largely unreliable as a means of inducing premature labour, though it is usually successful in initiating contractions at or after term.

The ideal method of induction, because of its ease and physiological sanction, would be some form of endocrine stimulation of the passive uterus. Our knowledge of the precision of action of the endocrine bodies, together with the absence of risk of infection, renders a method based on this principle highly attractive. The problem is wrapped up with that of the cause of the onset of labour and the maintenance of uterine contractions, about which we know little at present. Attempts to induce premature labour in women have not yet succeeded with sufficient uniformity to justify any clinical application. It is the obvious direction in which research on the clinical problem of induction of labour must be carried on.

INDICATIONS FOR THE INDUCTION OF LABOUR

TOXÆMIA OF PREGNANCY

When the group of diseases generally known as toxæmia are unrelieved by medical treatment, it is usually, if not always, imperative to terminate pregnancy. At what precise time during the course of any given toxæmia labour should be induced must depend upon many individual circumstances. Indeed, it may require the most experienced clinical judgment to arrive at a decision which, while safeguarding the interests of the mother, will also consider the chance of survival of the child. Whenever a pregnant woman develops albuminuria and a raised blood-pressure, the question of induction must arise, because it is seldom possible to cure, or even ameliorate beyond any threat of danger, the process of toxæmia. The problem is less *whether* induction shall be done, than *when* it should be done. A convenient way of

discussing the indications for the operation will be a description of the various *clinical types* with which we are confronted :

1. *The first group comprises all those cases which are first seen after the 36th week.* During the last four weeks of pregnancy the child's chances of survival are sufficiently good to save us from anxiety on its behalf, should induction be necessary. There need, therefore, be no desire to defer the operation, and so involve the mother in risk for the sake of the baby. In all cases of severe signs and symptoms, such as urine heavily loaded with albumen, high blood-pressure, vomiting, or marked œdema, labour should be induced at the earliest moment. The less serious cases should have a varying period of medical treatment, depending on the response of the physical signs, in order to detoxicate, as far as possible, before labour is induced ; but if there is the slightest sign of deterioration, or if any fresh symptom develops, labour must be induced at once. The general result of medical treatment of the milder cases is to produce a definite, though limited, improvement within 48 hours, but, after an initial fall in blood-pressure, reduction of albuminuria, and perhaps total disappearance of œdema, it is seldom that there is any further progress. The patient is still toxic, and probably still liable to eclampsia.

But even if we can say that the danger of eclampsia has been averted, we are still faced by the as yet unknown possibility of the danger of permanent damage to the kidney, which may be the result of continued albuminuria. The kidney which leaks albumen and discharges cellular casts is suffering from a functional strain. We have clinical evidence, obtained by following up the after-histories of eclamptic women, that the kidney may be impaired for many years. Should we not assume that, even though the sharpness of the strain in continued mild toxic albuminuria may not be so great as during the attack of eclampsia, yet the very chronicity of a stress of a milder degree may also impress a lasting strain on the kidney. I believe, therefore, that during the last four weeks it is a mistake to persist with medical treatment for more than a few days, even if improvement is quite definite. The very small group of patients who lose all their symptoms under the influence of medical treatment may be allowed to continue their pregnancy, but only under the strictest observation. If a woman has once had albuminuria she is liable to have a recurrence at any time until she is delivered. In general we may say that for toxæmia arising during the last four weeks, induction of labour will be necessary, either at once or after a brief period of detoxicating treatment.

2. *The second group includes those patients who become toxic before the 36th week.* The problem is now complicated by the fact that the child may die if delivered prematurely. Indeed, the risk of neo-natal death rises sharply for increasing prematurity before the 36th week. On the other hand, we must not forget that the fœtus *in utero* suffers a definite risk due to the influence of toxæmia. This is probably slight in cases of true toxæmia of pregnancy, for even in eclampsia there is a considerable survival of the children, but if a mistake has been made in the diagnosis, and instead of treating toxæmia we are actually dealing with chronic nephritis, the child is in grave danger of dying undelivered.

It is obvious that the earlier in pregnancy albuminuria first appears, the greater is the anxiety, partly because of the difficulty of maintaining the patient until the 36th week, and partly because the earlier it appears the more liable it is to be severe and progressive. For example, it is seldom possible to defer induction of labour if toxæmia first shows itself at or about the 30th week. The risk of persisting in medical treatment from the 30th to the 36th week is so great for the majority of such cases, that it is unjustifiable, and induction becomes imperative. Occasionally we meet with mild cases which react quickly to rest and depletion, but such are uncommon. The most difficult of all these problems is the patient who is a primigravida after some years of sterile married life. There can be few more anxious problems than this. We have seen the case of the childless woman, married for many years, who has had at least one operation and much other treatment for sterility. At long last she becomes pregnant. But about the 32nd week the blood-pressure rises and albumen appears. The usual medical treatment is successful for the first two days, and certainly reduces the symptoms, but they do not disappear and the patient is still obviously toxic. Meanwhile induction of labour will almost certainly sacrifice the child by prematurity, while continuance of pregnancy involves the mother in a steadily increasing risk. Each such problem must be considered on its individual merits, which are different in every case. There are many intangible factors, inherent in every family, which must be taken into consideration before the final decision on induction of labour can be made. In some cases these considerations will demand that the mother's endurance must be strained for the sake of the child, indeed she may easily decide the problem herself, while in other families the special effort must be devoted, by incubator and other unremitting care, to the struggle with prematurity.

The variation of special circumstances makes it impossible to give a detailed direction, but the writer feels that, where other things are

equal, the benefit of decision must always be given to the mother, not only if her life is threatened by the menace of eclampsia, but also because of the risk that she will carry the burden of nephritis for the rest of her life.

Where symptoms first appear at or after the 34th week, it is often possible to maintain the patient by careful treatment based upon daily watching of urine and blood-pressure until the 36th week, when labour can be induced, but if there is an increase in any of the original symptoms—which are usually albuminuria, raised tension, and œdema—or if any new symptom appears, such as vomiting, epigastric pain, or severe headache, then induction must be carried out at once. This rule is generally a safe one to follow in all cases of toxæmia. The "basal" state of the patient should be carefully noted after 48 hours of treatment, and further progress estimated from this datum line. We are fortunate in having two signs which are objective, and lend themselves to precise measurement. There are also other data such as the amount of urine, and its chemical constituents and blood chemistry which may also be taken into account, but we believe that it is unwise to be guided by chemical considerations alone. It is worth noting, in conclusion, that the patient's feeling of general well-being is not a guide to her clinical state. The majority of all women who show the three symptoms of raised tension, albuminuria, and œdema up to a moderate degree, never complain of any feelings of illness. In fact there may be a spurious sensation of increased vigour, due, possibly, to the rise in blood-pressure. This actually may cause difficulty, should the question of induction arise, in persuading the patient that the condition is sufficiently serious to demand termination of her pregnancy.

CONTRACTED PELVIS

We may say at the outset that induction of labour for contracted pelvis, or as it is often called "disproportion," is one of the chief controversial topics of obstetrics. The practice of different obstetricians varies between the two extreme poles of never inducing labour fo contracted pelvis, and of performing the operation for all cases whe the child can be delivered at or after the 36th week. Where opinio on lines of action for the same problem differ so markedly, we mu pause to think carefully. Either the results must be so nearly simila that either side must be equally correct, or else the practice of obstetri in this country must be such that neither school can be fully awa of the results of its own particular procedure.

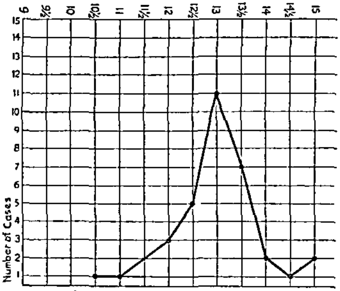
In the present section I shall attempt to discuss theoretical considera

tions, and produce figures which will provide evidence that induction should play only a minor part in the treatment of contracted pelvis.

In the first place let us attempt to define the clinical meaning of contracted pelvis and "disproportion." It is important to realise that the normal pelvis has a reserve space, or "room", beyond that required by the average child for safe passage. This is obvious if we place the fœtal skull in the dried pelvis in the flexed position. A certain amount of contraction, therefore, can occur without causing any embarrassment in labour provided, firstly, that it does no more than encroach on the reserve, and, secondly, that the child presents by the anterior well-flexed vertex. If, however, a pelvis is contracted to the limit of its reserve space, there would be real difficulty should any other abnormal condition co-exist, such as an occipito-posterior position, or a breech with extended legs. Manipulative treatment might be difficult, giving the impression that we were dealing with a case of disproportion in size between the fœtal skull and the pelvis. This view may be strengthened by noting that there is some reduction in pelvic measurements. Many such cases are labelled as cases of "disproportion," but actually it is not so much a case of lack of room in the pelvis, as of malpresentation of the head in a pelvis which has no reserve capacity to accommodate a mechanical abnormality. It is very true in obstetrics that a woman cannot carry two handicaps. She can manage delivery through a pelvis which has no reserve capacity, if the presentation be normal and the size of the child average, or an occipito-posterior presentation through a normal pelvis, but the two conditions together will cause trouble. The latter case is one of difficult labour, yet it is not really a matter of disproportion, though the suggestion may be strong. The same pelvis would pass the same baby in the flexed anterior position without difficulty. If, however, the pelvis is contracted beyond its reserve, then there will be trouble during the delivery of an average-sized baby, and here we have a true state of disproportion. It seems reasonable to say that if we can deliver the woman prematurely of a child a little smaller than the average we shall compensate for the contraction of the pelvis, and thereby enable her to deliver herself easily. There is no doubt that this can be done, and is done successfully, but we have to ask ourselves amongst other things, firstly, whether there is a greater risk either to mother or child if delivered by Cæsarean section, and secondly, whether induction at or after the 36th week can secure a child small enough to pass the brim and outlet of a pelvis which is truly and functionally contracted.

A study of the circumference of the heads of children delivered by

induction at or before the 37th week is instructive. A hundred consecutive cases have been taken from the records of a large maternity hospital. The results are as follows:



Size of circumference of Head at induction at 36 wks

CIRCUMFERENCE OF THE HEAD

Maturity 36th and 37th weeks

Circumference in inches	9	9½	10	10½	11	11½	12	12½	13	13½	14	14½	15
No. of cases	1	1	2	3	3	4	14	11	28	22	7	1	3

Of these cases, the three of 15 inches were of 36, 36, and 37 weeks respectively, while other inductions at 36 weeks produced children of the cephalic circumference shown in the table. Now the average circumference of the fœtal head at 40 weeks is 14 inches, which gives an average diameter of 4·45 inches, while the average circumference of the head delivered at 36 weeks is 13 inches, giving a diameter of 4·13 inches. There is therefore an average reduction of diameter in the region of 0·32 inch obtainable by induction of labour at 36 weeks. Not only is this reduction very small, but we find that of 33 fœtuses delivered at 36 weeks, 11 (or one-third) had a circumference of over 13 inches, and 10 below this figure. Two observations can be made from these figures: firstly, the wide variation in the size of the head at 36 weeks, i.e. between 10½ and 15 inches, and secondly, that induction performed 4 weeks before term, which is the maximum permissible time, will ensure an average reduction of one-third of an inch.

The argument, therefore, is that if a pelvis is sufficiently contracted to cause serious difficulty at term, it is unlikely that it will pass the child at 36 weeks sufficiently easily to give reasonable assurance of the easy delivery of a live child. The weights of the children delivered at 36 weeks are definitely less than those at term, but from the obstetric point of view it is not so much the weight of the child as the size of its head.

Much of the good reputation which has been claimed for induction for contracted pelvis is based upon the good results which have followed the operation performed for pelves which are not *functionally* contracted. But if an error has been made in the judgment of capacity for delivery, and a difficult forceps extraction becomes necessary for a fœtus of 36 weeks, it will, because of its greater fragility, suffer much greater risk from the stress of delivery than a full-term child which undergoes the same stress.

When considering the relative merits of induction and Cæsarean section in the treatment of disproportion, we must limit ourselves strictly to those cases of induction where there was no doubt that the pelvis was actually contracted. Hospital reports contain long lists of cases of disproportion where a scrutiny of the details shows that there was in fact no disproportion at all. For these patients induction was obviously unnecessary, even meddlesome, and the results should not figure in any statistical review. The mortality of Cæsarean section when undertaken before labour for contracted pelvis is about 1 per cent to 2 per cent, and for induction the added risk above that of normal labour is 0·23 per cent.

There is, therefore, a definite risk from induction for all cases done for "disproportion," as against a risk of about 1–2 per cent for the deliberate Cæsarean operation. But these figures are not a fair representation of the relative dangers. It is necessary to exclude all those cases of induction for so-called disproportion which did not actually exist, as proved by the conspicuously easy and short second stages of labour, described in various hospital reports. Where induction at 36 weeks is performed for true contracted pelvis, there is a considerable risk of a difficult delivery, and therefore a large enough series of these cases treated by induction of labour at the 36th week would probably show a greater mortality than the crude figures published by the hospitals.

Between the extreme views held by those who never induce labour for contracted pelvis and those who do it whenever possible, it is likely, on general principles, that there is a *via media*. The indications of the

operation depend, *inter alia*, upon the shape of the pelvis. The writer believes that for the true flat pelvis which holds the head above the brim and overlapping the symphysis it is bad treatment. The membranes will rupture early with the risk of prolapse of the cord, and the frail head of the premature fœtus will withstand the stress of moulding with little resistance. When the degree of flattening is sufficient to cause overlapping of the head at term, it will be probable that much moulding will be required to drive it through at or after 36 weeks. The problem of generally contracted pelvis is rather different. Here we find no disparity of "fit," for the shape of the brim is the same as that of the normal pelvis. During the last few weeks of pregnancy there will be an optimum moment at which the relation of the size of the head to the reduced but normally shaped brim will be the same as that of the normal head and pelvis at term. Labour at this moment should present the same risk therefore as at term, but it is, in fact, greater for the child because its softer head is less able to bear moulding. Nevertheless we believe that there are many women with mild degrees of general contraction who can safely deliver themselves of a child of about 6 lb., but who would have great trouble with one of 7½ or 8 lb. If induction is carried out for these patients, there is little or no risk of early rupture of the membranes or prolapse of the cord, as in the case of a flat pelvis.

We would sum up, therefore, by saying that, firstly, the greatest care should be taken to be sure that the pelvis really is contracted. As we have already said, very large numbers of women have labour induced for a disproportion which does not exist. The short period of the second stage of labour, the spontaneous delivery, and the unmoulded head are evidence of this contention. It is necessary to emphasise that the mere high position of the head above the brim does not by itself necessarily constitute evidence of contraction. There must be evidence derived from examination of the pelvis, not merely by measurement, which is misleading, but by careful internal exploration of the interior of the pelvic basin by the finger. Even difficulty in pushing a high head into the brim is not always a sign of disproportion. The difficulty may be due, not only to lack of skill in the manœuvre, but also to an unflexed state of the head. It is a common experience that at 36 weeks we may have decided to perform Cæsarean section for a case of high head which cannot be pushed down, but to our surprise, as term approaches, the head becomes fixed and engaged. This change may not become obvious until immediately before or even during labour.

Secondly, we may repeat that disproportion due to the large size

of the child's head where the pelvis is normal is extremely rare. But if the pelvic reserve is absent, naturally a large head will be disproportionate. In practice, however, the woman who has a generally contracted pelvis usually has a small baby, and therefore the large head is not often a cause of mechanical difficulty so long as it is well flexed and occipito-anterior.

True disproportion, or, as it is better termed, contracted pelvis, is far less common than many ante-natal workers think, but when it is discovered the treatment of choice is usually Cæsarean section. The fœtal results of induction of labour for contraction are given in the subjoined table, showing the risk to the child at the various stages of maternity.

Period of Gestation.	No. of Cases.	Fœtal and Neo-Natal Deaths.
40 weeks	120	19 (15·8 per cent)
39 „	52	6 (11·5 „)
38 „	132	9 (6·8 „)
37 „	47	5 (10·6 „)
36 „	59	9 (15·3 „)
35 „	4	2 (50·0 „)
34 „	12	5 (41·6 „)
32 „	4	2 (50·0 „)
30 „	2	0
28 „	1	0
24 „	1	1 (100·0 „)

The general results at Queen Charlotte's Hospital between the years 1908 to 1917 were that of 434 cases the maternal mortality was 0·23 per cent, of 340 fœtuses delivered spontaneously 10·8 per cent died, and of 94 delivered by forceps 17 per cent died.

ANTE-PARTUM HÆMORRHAGE

All cases of placenta prævia should have pregnancy terminated as soon as the diagnosis is clear. It may be a harsh decision where the mother has not quite reached 36 weeks, and the first and only bleeding has been unimportant. But it is certain that if induction is postponed some patient will, sooner or later, suffer the sudden fatal hæmorrhage. It is useless to expect that rest in bed or any form of treatment can exert the slightest influence, as the bleeding nearly always occurs while the woman is asleep in bed.

The case of accidental hæmorrhage (abruptio placentæ) is rather different. Here the underlying condition is often toxæmia, which, if treated, will prevent further bleeding. Other patients have only small

trifling hæmorrhages which, though they may persist for some days, are seldom a cause of danger, and are readily amenable to treatment by rest and detoxicating measures. There are some severe cases of accidental hæmorrhage, again usually due to toxæmia, which must be treated by methods which will have, as their immediate object, the relief of shock, the arrest of hæmorrhage, and, incidentally, induction of labour. It should be clearly understood that neither for placenta prævia nor for grave accidental hæmorrhage should labour be induced as a primary method of treating hæmorrhage. Though it is true that the result of treatment will ultimately be the termination of pregnancy, yet the measures adopted are chosen from the point of view of arrest of bleeding and not as the quickest method of inducing labour. The onset of labour is an incidental and, indeed, necessary result, but it is not the primary consideration.

THREATENED DEATH OF THE FŒTUS

Occasionally a woman may repeatedly give birth to dead children at or about term for no apparent reason. The most careful examination for nephritis, syphilis, or deformities, fails to find any evidence of these conditions. The mother reports cessation of movements during the last 2 weeks, and a few days later a dead baby is born. The risk of yet another still birth may sometimes be overcome by induction of labour at the 36th week, or at a time just before previous deaths have occurred. This is not always successful, but there is a better chance of obtaining a live baby than by allowing pregnancy to go to term.

POST-MATURITY

The calculated date of labour obviously gives only an approximate idea of the real date of full term. Our knowledge of the time of ovulation makes it clear that the end of the 40th week may follow as much as 2 weeks after the calculated date of term, and therefore it is not possible to diagnose post-maturity until at least 2 weeks have passed beyond the woman's "date." Further, there is always the possibility that she has made a mistake of even a month in the date of the last menstruation. It is probable that real post-maturity is uncommon, and that it is not enough that the calculated date has been passed, to diagnose post-maturity. Until 2 weeks have passed, therefore, there is no real indication for interference. Occasionally, however, special circumstances of the individual case may warrant induction of labour. For example, the woman may be of that nervous or impatient temperament which frets at the delay to such an extent that induction must

be performed. Or there may be circumstances of nothing more than convenience which, in an individual case, may justify the operation. In general, however, we may say that during the first fortnight after the calculated date nothing should be done so long as the general and local conditions are satisfactory. Provided the woman is well, and the head either engaged or fairly easily pushed down into a normal pelvis, there need be no anxiety during the first 2 weeks. After this, the question of post-maturity may actually arise. Should the correctness of the date of expectation be beyond a doubt, it is probable that the third week past " term " represents the first week of post-maturity. A fat,

CASES OF INDUCTION OF LABOUR FOR ALLEGED POST-MATURITY

Weight.	Circumference of head in inches	Duration of second stage.
10 10	15	1.35′
9 3	15	10′
7 5	14	40′
6 10	15	1.12′
8 4	15	37′
7 11	14½	50′
7 2	13½	1.10′
8.12	14½	30′
6 5	14½	55′
8 8	14	1 0
6.3	14½	20′
10 4	15½	10′
6 4	14½	1 30′
6 9	14	15′
9 4	14½	1 0
8 8	15	2.0
7.7	?	1.0
6 0	14	20′

sedentary, lazy woman is liable to go beyond her real term—in such a case a short period of post-maturity may be expected. Secondly, the size of the child and its head should be noted. Whereas it is impossible to estimate the weight of the child accurately before delivery, yet extremes of size are obvious. If the uterus is clearly small for the apparent date, or if the palpable diameter of the head is not larger than normal, post-maturity does not exist or, shall we say, even though the scheduled number of weeks have been passed, the maturity of the child's development is not too advanced for its safe delivery. But there are some patients in whom the abdomen is distended by a large, tense uterus, containing not an excess of fluid but an undeniably large baby.

The head also feels wide, large and hard. We feel that for this woman labour should be induced at the end of 2 weeks, if not before. As the method of choice in these cases is by castor oil and other drugs, there is not the same objection to induction as when bougies or tubes are inserted into the uterus.

Evidence of the frequent incorrectness of the diagnosis of post-maturity is supplied by the table (on preceding page) of consecutive cases of induction for "post-maturity", taken from the records of a maternity hospital for 1933 and 1932. The length of all the pregnancies is described as "40" weeks. It will be noted that only 7 out of 11 babies weighed $8\frac{1}{2}$ lb. or more, and only two could be described as very heavy children. The circumference of the head was unduly large in only one child ($15\frac{1}{2}$ inches), and in this labour the second stage lasted only ten minutes, while in the majority this measurement was either within or below normal limits. The times of the second stage of labour, all spontaneous, are further indications of the absence of the difficulty which was anticipated by those who induced labour.

ASSOCIATED DISEASES

It is a generally true principle that when pregnancy complicates, or is associated with, a pre-existing disease or one developing during the course of pregnancy, it is usually wise to treat the disease and leave the pregnancy alone. There are, however, some well-defined exceptions, chief amongst which are chronic nephritis, certain cases of cardiac disease, diabetes, depression, goitre, and many other conditions represented by an occasional example. The individual circumstances of almost every disease may specially conspire to render induction advisable in the exceptional case, but nevertheless it is a general rule that, except for nephritis and cardiac disease, induction is seldom required. Indeed it is true that in many cases not only should induction not be performed, but every effort made to prevent the onset of premature labour. This is generally true of all acute infections such as influenza and the great majority of all cases of pyelitis. Some diseases may be actually "improved" by pregnancy, an example of which is hypochlorhydria, while a notable exception is phthisis, where not only no good but actual harm may be caused by induction after the third month.

In chronic nephritis, however, the condition is definitely exacerbated by pregnancy, not only for the time being, but permanently. The mother will suffer by the continuation of her pregnancy and there will be a large risk of the death of the fœtus *in utero*, at a time depending upon the severity of the disease. Induction, therefore,

though terminating pregnancy before the child has a chance of survival, does not often deprive her of a child which she would have had if induction had been withheld. It is probably true that every case of chronic nephritis should have labour induced during the last 4 weeks, not only for the sake of the mother, but also to save the baby from probable death *in utero*. Before the 36th week there may be some effort made to treat by medical measures until this date has been reached, but, generally speaking, we should say that there is far less latitude for temporising than in the case of true toxic albuminuria. Opinions differ in respect of heart disease. The problem is not quite the same as in induction of abortion. When the child has passed the period of viability, every effort should be made by rest, digitalis, and symptomatic treatment to nurse the heart into some degree of compensated efficiency. It may be that by reason of hydramnios or other obstetric conditions induction would be advisable, but, as a general rule, it is better to allow pregnancy to proceed to term. There are, however, exceptions. For example, a multipara with a history of previous easy labours, who is finding the last month a great burden, even though in bed, may have the membranes ruptured. This, provided other details are normal, will ensure that she has a quick and easy labour. In no circumstances should labour be induced during any acute attack of heart failure, and in all cases only after some days of treatment in bed by digitalis. If possible all symptoms of failure, such as irregularity, œdema, albuminuria, and cardiac pain, should have disappeared.

With regard to all other associated diseases every case should be judged individually. Two questions must be asked: First, is the progress of the disease advancing by reason of the pregnant state? Second, will the operation of induction of labour actually relieve the strain or will it not only add to the stress but also fail to relieve even though pregnancy be shortened?

INDUCTION OF LABOUR

Methods

1. *Induction by Drugs.*

The desire to avoid local interference, with its obvious disadvantages, has led to many attempts to provoke uterine action by drugs. Of these castor oil, quinine, and pituitary extract, together with enemata and hot baths, have been used in varying methods and combinations. It is probable that quinine has a bad effect on the fœtus—evidence has been brought forward to show this—whereas its effect on uterine contraction is to render it uneven and not stronger. It should be

discontinued. Both castor oil and pituitary extract will frequently start contractions at or near to term, and especially if the date of term has been passed, but unfortunately this method is most unreliable as a means of inducing labour at or before the 38th week. Moreover, it is somewhat exhausting for the woman, especially when it has to be repeated. In the writer's opinion it is of little value except for post-maturity, or as a means of starting labour at term for the sake of convenience. There are some cases of toxæmia which may be so treated, but, as a rule, a better method is rupture of the membranes.

A specimen of the time-table of the so-called drug induction is as follows:

8.0 a.m.	Castor oil	1½ ounces.
12.0 noon.	Simple enema.	
2.0 p.m.	Pituitary extract	5 units.
3.0 p.m.	,, ,,	5 ,,
4.0 p.m.	,, ,,	5 ,,

The injections of pituitary extract may be repeated each hour without danger, but if no contractions appear in response to these injections, it is useless to repeat them. Occasionally, a few slight pains will follow about ten minutes after each injection, only to die away in half an hour. Should this occur, it is worth while repeating the whole treatment in 48 hours. The results are as follows:

Of 50 cases for whom this method was used at or before the 38th week, it was successful in provoking contractions in 34 (or 68 per cent). When the method is successful, pains usually begin during the course of treatment, or, if not then, within a few hours after the last injection. In some clinics thymophysin is used instead of pituitary or pitocin, but there seems to be little difference between the two preparations.

2. *Rupture of the Membranes.*

This is probably the oldest method which has been employed. During recent years it has been revived as an alternative to the use of bougies or stomach tube, and favourable reports have been published. There has been a theoretical prejudice against artificial rupture of the membranes because of the fear of depriving the cervix of its natural dilator, and so delaying the first stage of labour. If delay occurs, other dangers also arise such as prolapse of the cord, pressure on the fœtus, and infection. It is a fact, however, that nearly all multiparæ and very many primigravidæ whose membranes rupture at the beginning of labour not only have no delay, but may even have a quicker labour than normally.

But though for certain cases it is a successful and generally satisfactory method, yet it is important that the cases should be carefully chosen. If the head is engaged in a normal, flexed, anterior position, and especially if the woman is a multipara, rupture of the membranes is the easiest, quickest, and most certain method of inducing premature labour. The cases which present these favourable conditions and which require induction are chiefly those of toxæmia, and, in addition, toxæmia is sometimes complicated by hydramnios, for which rupture of the membranes is good treatment. The escape of excessive fluid frequently has a beneficial effect on toxæmia, apart from any other treatment, which is a further reason for rupture of the membranes.

But for disproportion or contracted pelvis the conditions are very different. Here the head is high, and rupture of the membranes before labour will leave no dilating surface to occupy the cervix. This alone tends to delay the onset of useful contractions. The high head will also not form the normal barrier to prolapse of the cord, or to the escape of all the liquor amnii. The uterus is then " dry," and the baby is grasped dangerously by the contracting fundus. Rupture of the membranes is a useful method for post-maturity and for most cases of associated diseases for which labour must be induced if drugs have failed. This minor operation may be difficult unless the patient is in a convenient position, often under an anæsthetic, and there is a good light and suitable instruments. In order to be sure of cleanliness it is necessary to operate by sight, through a speculum. This can usually be done in multiparæ without an anæsthetic, but primigravidæ may be too intolerant of the discomfort.

The procedure is as follows: The woman may have to be anæsthetised. She is placed in the lithotomy position or on her left side, according to the custom of the operator. The vagina is swabbed with iodine, or perhaps better with dry sterile gauze. The cervix is lightly held by vulsella, and a pair of toothed forceps or vulsella is passed through the os, and opened and closed gently on the fœtal head. This usually means that the membranes will be caught and broken, but it may be necessary to make several attempts before they can be ruptured. It is useless to push in a blunt instrument like a sound, for the amnion is usually too tough to yield. A primigravida may require a little dilatation of the cervix before toothed forceps can be introduced. After the escape of liquor shows that the membranes have been punctured, the head should be held up off the os by the finger to allow the escape of a portion of the liquor. Unless this is done, the liquor may dribble away so slowly that the uterine contents are not reduced quickly

enough to stimulate the rapid onset of pains. The results of this method are as follows:

Parity.	Average time *before* onset of pain.	Extremes of *times before* onset of pain.		Average duration *of* 1st Stage.	*Shortest* 1st Stage.	*Longest* 1st Stage.	Average duration *of* 2nd Stage.
		Long.	Short.				
26 Primip.	14 h. 25′	88 h.	1 h.	16 h. 13′	1 h. 20′	72 h.	3 h. 8′
21 Multip.	12 h. 55′	66 h.	½ h.	5 h. 28′	1 h. 10′	23 h.	30′

There was no maternal mortality.

Still births and neo-natal deaths—20 per cent.

Inductions were performed for disproportion, post-maturity, toxæmia, pyelitis, hydramnios (1 case), and cardiac disease (1 case), and no other method was used for this series but rupture of the membranes.

A glance at the table shows a reasonable time before onset of pains, and a first stage not differing from that of normal labour. The long extremes of times in both cases were exceptional. The fœtal mortality was high and was associated with the following conditions:

Albuminuria	9
Dead fœtus before labour	3
Eclampsia	2
Post-maturity	1
Hydramnios	1
Anencephaly	1
Graves' disease	1
Unstated	2

3. *Bougies (Krause's method).*

The principle of this method is the introduction of a foreign body into the uterus whereby irritation will set up contractions. For many *years this has been the method of election in all cases requiring induc*tion, but recently it has to some extent been supplanted, especially in hospitals, by drugs or rupture of the membranes. It is chiefly useful where it is desired to retain the membranes intact, as for contracted pelvis, or where drugs have failed, or before the 38th week when drugs are not likely to produce labour in more than 68 per cent of cases. It is carried out as follows: In order to ensure asepsis, an anæsthetic is usually necessary, and, as before, the patient is placed in the lithotomy position and disinfected. The cervix is lightly held by vulsella, and sometimes requires dilatation. If possible the finger is passed through the os in order to separate the membranes around the os. This may have some effect in stimulating the onset of pains. Four

bougies of gum elastic are now carefully passed, one by one, through the os until their heels are well within the uterus. The vault of the vagina is then lightly packed with gauze soaked in acriflavine. Bougies should be sterilised by keeping them in a long glass tube saturated with formalin vapour. Special glass containers are made for this purpose, or, if not available, the bougies should have been kept overnight in a solution of biniodide of mercury, 1 in 500. Heat renders them too soft for use. Certain difficulties are occasionally encountered: resistance to the passage of the bougie may be felt after it has passed two or three inches within the os. This is almost always due to its impinging on the edge of the placenta. No further force should be used, but other bougies inserted in different directions. Occasionally a brisk hæmorrhage occurs as the bougie is being passed. This indicates that it has passed under the placenta. It should be removed at once, the membranes ruptured, and the vault of the vagina packed unless the bleeding stops quickly. It usually ceases almost at once, and no serious results ever follow. There is very little danger of sepsis if the bougies have been carefully sterilised, if they have been passed straight into the cervix without touching the vagina, and if the cervix is uninfected.

The chief disadvantage of this method, apart from the fact of local interference, is the uncertainty of the time of onset of contractions. Pains usually begin within three days, and often within twenty-four hours if the patient is near to term, but it sometimes happens that five days have passed and still labour has not begun. On the fourth day it is well to give a large dose of castor oil, and on the fifth day to remove the bougies and rupture the membranes. A further disadvantage of the method when it fails after having been done for contracted pelvis is that the presence of the bougies within the uterus for five days renders Cæsarean section an unsafe operation because of the danger of infection.

4. *The Hydrostatic Bag.*

Many varieties of water-filled rubber bags have been invented for introduction through the os into the lower segment. The best known are those of de Ribes and Horrocks, but there are others commonly used which are simple rubber balls, filled through a long tube, and containing about 4 or 6 ounces. The de Ribes bag, made of silk and rubber and shaped to occupy the lower segment, contains 17 ounces. It is introduced by a special forceps-holder through the cervix, which, after the membranes have been ruptured, must be dilated to allow two fingers to pass. It is then slowly filled by a Higginson syringe. It displaces the presenting part and lies accurately in the lower segment. The

presence of so large a foreign body within the lower segment quickly stimulates the onset of contractions and dilatation. The de Ribes bag is seldom used for inducing labour, except for certain cases of placenta prævia, but even for this it has been largely given up in recent years.

There is less objection to the use of the small round bag, which is somewhat smaller than a tennis ball. A good form of this is the ball pessary. The os need not be larger than will admit one finger, the membranes need not be ruptured, and it does not displace the presenting part so greatly as the de Ribes bag. It is quite certain in its effect, for the onset of labour is rarely delayed beyond 24 hours.

There are, however, various objections to the use of bags. They perish easily and are therefore liable to leak. This, apart from destroying the essential value of the apparatus, involves a danger of sepsis. The introduction of the bag always requires an anæsthetic and some dilatation of the cervix. It is possible for the bag to be displaced to one side, allowing the head to descend and press upon the neck of the bag, thus preventing it from being expelled, while the presence of the bag also prevents the head from dilating the os. A form of obstructed labour can thus arise. The only advantage of the de Ribes bag, apart from its use for placenta prævia, is for those cases of disproportion where the head is high and cannot come down to dilate the os until it has been well moulded. This bag will dilate the os to a diameter of 3 inches during its expulsion, and so prepare the way for the descent of the head.

On the whole, bags are not used much for induction of labour. Simpler methods should be employed.

5. *Endocrine methods.*

Experiments on animals with the ovarian hormones raised the hope that it would be possible to stimulate the onset of labour by giving injections of œstrin. The earlier experiments all failed because the dose was too small. But doses up to one million units have failed in the writer's hands, even when combined with pituitary extract. It is possible that still larger doses may succeed, but though there is a promise in this direction there is no certain evidence that human premature labour can be induced by œstrin.

CHAPTER II

VERSION

VERSION is probably one of the oldest of all obstetric manipulations. It is concerned with changing the presentation of the fœtus, either because its delivery in the unaltered position would be difficult, or because the new position would form a useful treatment for placenta prævia, flat pelvis and other conditions. The varieties of the manœuvre are described as external, bi-polar, and internal.

EXTERNAL VERSION

Before or at the onset of labour the child may be turned by manipulation of its head and breech, applied through the abdominal wall. It is nearly always done to change a breech presentation into a vertex, but occasionally for placenta prævia to produce a breech presentation, preparatory to pulling down a leg. For breech presentation it is the usually accepted treatment if the presentation is discovered before the 38th week, but after this date it is often impossible owing to lack of easy mobility of the child. The difficulties attending successful version are due to extended legs, relative lack of liquor amnii, twins, and tense uterine or abdominal walls. Sometimes an anæsthetic will enable it to be carried out successfully by abolishing the tone of the abdominal wall. Engagement of the breech within the pelvis, usually associated with extended legs, is a frequent cause of difficulty, though this can often be overcome by using the Trendelenburg position and an anæsthetic. The rate of success in all attempts is as follows:

Total No. of cases.	Failure.	Number turned under anæsthesia	Spontaneous version before term, after failure	Still birth following failure of version
233	42 (18%)	55 (23%)	10 (out of 42) (24%)	11 (out of 42) (26%)

These figures show a higher rate of success than is usual, and probably a higher tendency towards the use of anæsthetics than in most clinics. It will also be noted that, even when external version fails, about a quarter of the cases undergo spontaneous version. Whether this would have happened in any case, or whether it is a result of the

disturbance of the fœtus caused by the efforts to turn, cannot be stated, but it may be assumed that, even if there is little prospect of turning the child, it is worth while making the attempt, for even if it fails, spontaneous version can occur during the following few days. The *raison d'être* of the operation is based upon the high mortality of children delivered by the breech. In some clinics this is as high as from 20 to 30 per cent. The mortality of children delivered by the vertex is much lower, and hence the advisability of changing the presentation wherever possible. But it must not be assumed that the fœtal death-rate of the vertex deliveries after version is identical with that of normal vertex. Figures published by Wrigley (*B.M.J.*, May, 1934, 893) state that, of 45 patients for whom version was performed under anæsthesia, 10 had still-born children, usually macerated. That is, the fœtal mortality of vertex delivery after successful version under anæsthesia was as high as 21 per cent. Of 19 cases in which version failed, all the children were born alive! There are definite dangers attending external version when it is performed without care. Too forcible manipulations are liable to separate the placenta, or even to damage the uterine wall. The fœtus is always distressed to some extent during the manœuvre, as can be shown by the state of the fœtal heart both before and after. It is probable that too rough or prolonged efforts may kill the fœtus, or a true knot may be formed in the cord. A safeguard against too forcible handling of the uterus is the woman's sensation of pain, which is not available if the patient is anæsthetised.

In addition to breech presentations, all shoulder presentations should be turned to the vertex position wherever possible.

METHOD

The time of election is at or about the 36th week. Before this time the fœtus is liable to undergo spontaneous version, whereas afterwards the relative size of the child to the amount of liquor amnii increases sufficiently to destroy its mobility. The woman is best placed in a slight Trendelenburg position, and according to the opinion of many it is an advantage to anæsthetise her. The writer's own belief is that it is safer not to give an anæsthetic. The abdomen is examined to find the lie of the child, as it is important to turn the child in the direction in which its face is looking in order to keep the fœtus flexed. The operator stands on the side on which is the child's back, and applies both hands to the breech in an attempt to lift it out of the brim on to the iliac fossa (fig. 2117). This may be impossible, and if so, then no further efforts to turn it will succeed. When the breech has been brought on to

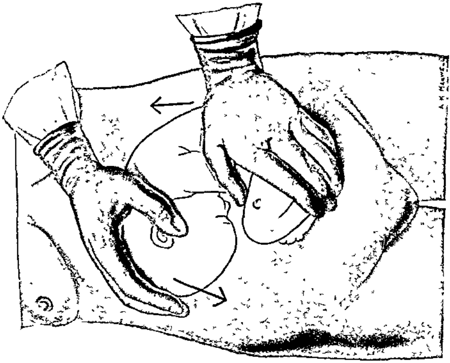


Fig. 2118.—The second step in external version. Having "scooped" the breech into the iliac fossa, the right hand is removed to push the head down from the fundus, while the left hand holds the breech from slipping back into the pelvis.

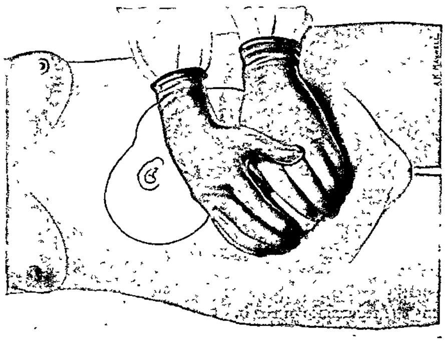

Fig. 2117.—The first step in external version. The operator, standing on the same side of the patient as the child's back, applies both hands to the breech in order to "scoop" it out of the brim into the iliac fossa.

the iliac fossa it is held there by one hand, while the other hand presses down the head to bring it towards the brim (fig. 2118). At the same time the breech is lifted up towards the fundus (fig. 2119). The movements imparted to the fœtus should be more those of intermittent than of continued pressure. It is often possible to bring the child into the

transverse position, but impossible to bring the head down on to the brim.

This may be due to extended legs or occasionally to twins. After the version has been completed, a tight binder is applied and a folded towel placed in each iliac fossa to maintain the head over the brim for 24 hours. In most cases the breech position will not recur, but if after a few days a further examination finds the head in the fundus, a flat pelvis or placenta prævia should be suspected unless hydramnios or

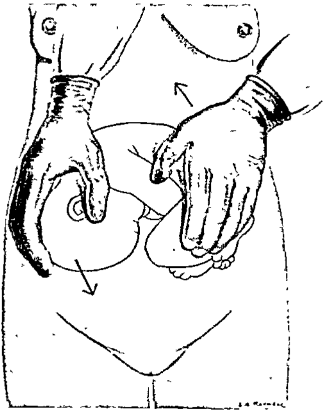

Fig. 2119.—External version. As the right hand pushes the head down towards the brim, the left hand is lifting the breech up to the fundus. The final stage is reached as the head rests over the brim, and the breech is in the fundus.

undue prematurity is sufficient to render the child unusually mobile. Recurrence often follows a version which has been very recently performed, but when there has been much difficulty the vertex position is permanent. If recurrence of the breech position should follow, it is well to wait a few days and then to turn the fœtus again.

BI-POLAR VERSION

After labour has begun it is usually impossible to perform external version because of the irritability of the uterine wall, but it is still possible in certain cases to turn the child before full dilatation, provided the os will admit two fingers. It is always done to convert a cephalic

presentation into a breech, generally with the object of bringing down a leg. The chief indications are selected cases of placenta prævia, prolapse of the cord and face, and brow or shoulder presentations. When first introduced by Braxton Hicks it was a considerable addition to the manipulative treatment of obstetrics, especially for placenta prævia, and, in those days, for flat pelvis. In recent years, however, it has been less used, chiefly because many of these abnormalities are treated by Cæsarean section or by other methods. There is no doubt, however, that it is a very valuable method for dealing with many cases of placenta prævia, and it is probable that in time it will again figure in the reports of maternity hospitals. The statistical results for the mother are good, but for the child they are not so promising, chiefly because it is usually undertaken for quite premature children whose chance of life is in any case slender. Despite the increasing use of Cæsarean section and its *prima facie* appeal to the obstetrician, there is a definite field for the practice of bi-polar version in the treatment of placenta prævia. A multipara, first seen when the os will admit two fingers, with a placenta felt at its margin or even completely covering it, and of maturity of 36 weeks or less, is usually a suitable case for treatment by bi-polar version. If such a patient, who has already suffered sufficient hæmorrhage to produce an obvious anæmia, is found in circumstances where laparotomy would be unwise, or transport difficult, bi-polar version is by far the safest treatment. We would go further and say that the graver the anæmia, the wiser it is to perform a manœuvre which will certainly arrest further bleeding and involve the least shock. The real disadvantage of the method is actually its difficulty. In some cases where the os easily admits two fingers and the child is small and mobile it is a simple manœuvre, but it is often difficult enough to occupy several minutes, and so provoke further bleeding from the lower segment. This is the crux of the difficulty. The disturbance of the os, placenta and lower segment will cause additional bleeding, and if version requires more than a few minutes a fatal hæmorrhage may occur. A considerable advantage of the method is that when the leg has been brought down there is almost no risk of further hæmorrhage. It is impossible or unsuitable before the os will admit two fingers or when it is large enough to admit the whole hand for internal version, also if the child is large enough (or the liquor has escaped) to render it immobile. Free mobility is a necessary condition for performing the method safely and expeditiously.

Other indications for which it might be advantageous to convert a vertex to a breech presentation when the os will only admit two

fingers are certain cases of face and brow presentations, prolapse of the cord, and flat pelvis. As flat pelvis may be found associated with these presentations as a cause thereof, it is important, before version is contemplated, to be sure that the degree of contraction is not so great as to make safe delivery of the after-coming head impossible. *Version* for flat pelvis, apart from associated malpresentation, was often employed formerly as a sound method of treatment, and many of the more senior practitioners of to-day still favour it. Provided that the true conjugate is not too seriously contracted, say, not below 3½ inches, there is a mechanical advantage in extracting the after-coming as opposed to the fore-coming head because of the narrower wedge offered by the after-coming head to the pelvic brim. Where brow presentation, uncomplicated by flat pelvis, is first seen after the woman has been in labour long enough to dilate the os to the size of two fingers, bi-polar version may, by abolishing an obstructing position of the head, be the *least risky method of delivery. Face presentation should be delivered* as such, provided that the pelvis is normal, but if, as often happens, there is a mild degree of flat pelvis, version may be considered as the best method of overcoming both the malpresentation and the pelvic contraction. The ideal combination of circumstances as an indication for bi-polar version must, however, be very uncommon in these days of ante-natal examination and Cæsarean section.

The case of prolapse of the cord is rather different. If the pelvis is normal or mildly flat, and the cord cannot be successfully pushed up, the tendency for the cord to prolapse can be prevented by turning the child and pulling a leg through the as yet imperfectly dilated os. Such treatment is specially indicated where the pelvis and the child are of normal size and the woman is a multipara. The point against version is that we are thereby producing a presentation which carries a high degree of risk for the child, but if the cord cannot be maintained above the presenting part, the child will certainly be lost unless something drastic is done. In general, it may be said that bi-polar version competes with Cæsarean section as a method of treatment, but because of the extended scope of this operation by the technique of the lower segment incision, bi-polar version has been less and less employed during recent years. There is no doubt, however, that the stage of labour at which bi-polar version may be called for is often one carrying much risk if Cæsarean section is performed, and version is undoubtedly the safer method. This is particularly the case in placenta prævia where the placenta is marginal, and the baby is premature and small. This may also apply to some cases of prolapse of the cord where, other things

being normal, the child is already in a condition of distress. The chance of delivering a live child, already shocked or distressed, by Cæsarean section is small, whereas, though version may add something to the shock, yet the rest *in utero* which follows version with the cord replaced will allow sufficient recovery before the stress of delivery is at hand. If the child is in good condition and the membranes have not ruptured for more than two hours, and if there has been nothing but the minimum and cleanest vaginal examination, then Cæsarean section is, on the whole, the better treatment, but if the child's chances are poor, and if the mother is a case of "suspect sepsis," then, as a rule, bi-polar version is the better method for the indications already mentioned.

METHOD

Certain conditions of labour must be present for the successful performance of bi-polar version. For example, the os must be large enough to admit at least two fingers, and the child must be freely movable. If the membranes have been ruptured long enough to allow the liquor amnii to drain away, and if, in addition, the uterus is contracting firmly on the child, it will not be sufficiently mobile to allow of version under the comparatively feeble impulse that can be effected by the action of two fingers. For this is one of the chief difficulties of bi-polar version. Two fingers passed through the os cannot press strongly enough on the accessible part of the fœtus, and if it is not readily mobile it cannot be turned.

A second difficulty is inaccessibility of the child's elbow or knee. These parts of the body may not be reached sufficiently easily by the tips of the fingers to receive a strong enough thrust. But despite these two chief difficulties, the operation is simple and can be quickly performed in properly chosen cases.

The steps of the technique are as follows: A careful abdominal examination is made to determine on which side lies the back, for, if the back is to the right, the operator must use his right hand, and his left hand when the back is to the left. The woman is anæsthetised, set in the lithotomy position, disinfected in the usual way, and catheterised. If the position is such that the back of the fœtus lies to the mother's right, the operator passes his right hand into the vagina and two fingers through the os. If the membranes are intact they are ruptured, and the head is pushed into the right iliac fossa (fig. 2120). Meanwhile the operator presses the fundus of the uterus firmly to push the breech down and to the left. When the head has been dislodged into the iliac fossa, pressure by the left hand on the breech

INTERNAL VERSION

When the os is dilated enough to admit the whole hand, version can be performed by passing it towards the fundus, grasping a foot and bringing it straight down to, and through, the os. It is therefore only possible to employ this method towards the end of the first stage. Under suitable conditions it is a safe, quick, and easy operation, but if the uterus is firmly contracted after a long obstructed labour it is highly dangerous in that it is likely to rupture the lower segment of the uterus.

Indications.—Now that Cæsarean section is so widely used for abnormal conditions, internal version is not employed as much as formerly. Ante-natal treatment has also reduced its application in correcting the shoulder presentation, but there are still cases seen for the first time in which the os is nearly fully dilated, where internal version is ideally useful. The chief example of these is the *shoulder presentation.* If the uterus relaxes between the contractions sufficiently to allow the fœtus to be moved easily, the operation is simple and safe, but if the lower segment has already been unduly stretched by strong contractions which do not relax their grip on the fœtus, the attempt to turn is dangerous because the thin lower segment will almost certainly

being normal, the child is already in a condition of distress. The chance of delivering a live child, already shocked or distressed, by Cæsarean section is small, whereas, though version may add something to the shock, yet the rest *in utero* which follows version with the cord replaced will allow sufficient recovery before the stress of delivery is at hand. If the child is in good condition and the membranes have not ruptured for more than two hours, and if there has been nothing but the minimum and cleanest vaginal examination, then Cæsarean section is, on the whole, the better treatment, but if the child's chances are poor, and if the mother is a case of "suspect sepsis," then, as a rule, bi-polar version is the better method for the indications already mentioned.

METHOD

Certain conditions of labour must be present for the successful performance of bi-polar version. For example, the os must be large enough to admit at least two fingers, and the child must be freely movable. If the membranes have been ruptured long enough to allow the liquor amnii to drain away, and if, in addition, the uterus is contracting firmly on the child, it will not be sufficiently mobile to allow of version under the comparatively feeble impulse that can be effected by the action of two fingers. For this is one of the chief difficulties of bi-polar version. Two fingers passed through the os cannot press strongly enough on the accessible part of the fœtus, and if it is not readily mobile it cannot be turned.

A second difficulty is inaccessibility of the child's elbow or knee. These parts of the body may not be reached sufficiently easily by the tips of the fingers to receive a strong enough thrust. But despite these two chief difficulties, the operation is simple and can be quickly performed in properly chosen cases.

The steps of the technique are as follows: A careful abdominal examination is made to determine on which side lies the back, for, if the back is to the right, the operator must use his right hand, and his left hand when the back is to the left. The woman is anæsthetised, set in the lithotomy position, disinfected in the usual way, and catheterised. If the position is such that the back of the fœtus lies to the mother's right, the operator passes his right hand into the vagina and two fingers through the os. If the membranes are intact they are ruptured, and the head is pushed into the right iliac fossa (fig. 2120). Meanwhile the operator presses the fundus of the uterus firmly to push the breech down and to the left. When the head has been dislodged into the iliac fossa, pressure by the left hand on the breech

brings the elbows within reach of the two fingers, which, in their turn, are also pushed towards the right iliac fossa (fig. 2121). If the child is not freely mobile within the uterus, this movement is difficult and may be impossible, but in successful cases the displacement of the elbow to the right pushes the head out of the iliac fossa into the flank. The fœtus is now transverse, and above the fingers lies the abdomen. Further

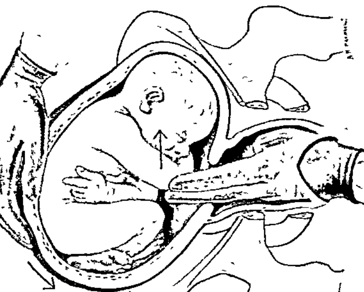

Fig. 2121.—Bi polar version. The head has been pushed to the left side, by which movement the elbow has been brought within reach of the fingers. In the same way the elbow is also pushed away to the left, while the breech is pushed firmly down on the right side towards the brim.

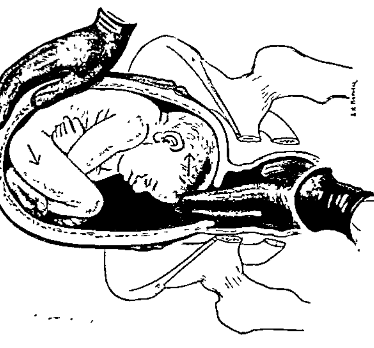

Fig. 2120.—Bi polar version. First stage: Two fingers passed through the os push the head into the iliac fossa, while the right hand pushes the breech out of the fundus. Note that the operator introduces the fingers of the left hand when the child's back lies to the left.

METHOD

The woman is anæsthetised and prepared as already described, and the gloved hand is passed slowly up through the cervix, displacing the head or shoulder to the side on which lies the back. The operator may use either hand according to the side of the child's back.

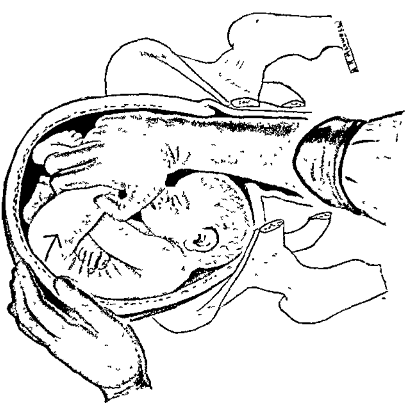

Fig 2124.—INTERNAL VERSION. THE RIGHT HAND IS PASSED UP INTO THE UTERUS TO GRASP THE NEAREST KNEE, WHILE THE LEFT HAND PRESSES THE BREECH TOWARDS THE INTERNAL HAND

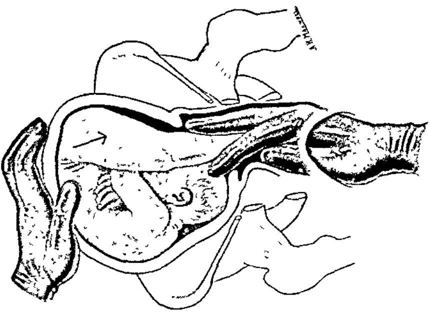

Fig 2125.—INTERNAL VERSION. THE GRIP OF THE FOOT AND PRESSURE ON THE BREECH AT THE FUNDUS

INTERNAL VERSION

When the os is dilated enough to admit the whole hand, version can be performed by passing it towards the fundus, grasping a foot and bringing it straight down to, and through, the os. It is therefore only possible to employ this method towards the end of the first stage. Under suitable conditions it is a safe, quick, and easy operation, but if the uterus is firmly contracted after a long obstructed labour it is highly dangerous, in that it is likely to rupture the lower segment of the uterus.

Indications. Now that Cæsarean section is so widely used for abnormal conditions, internal version is not employed as much as formerly. Ante-natal treatment has also reduced its application by correcting the shoulder presentation, but there are still cases seen for the first time in which the os is nearly fully dilated, where internal version is ideally useful. The chief example of these is the *shoulder presentation.* If the uterus relaxes between the contractions sufficiently to allow the fœtus to be moved easily, the operation is simple and safe, but if the lower segment has already been unduly stretched by strong contractions which do not relax their grip on the fœtus, the attempt to turn is dangerous because the thin lower segment will almost certainly be ruptured.

If the conditions are suitable, internal version may be performed for *brow* and *cord presentations,* if other methods have failed. There are also a few rare cases of *placenta prævia* which have not been previously or adequately treated and in which hæmorrhage is still threatening. If in such patients the os will admit the hand, a rapid internal version can be carried out, the breech can be pulled well down into the pelvic cavity, and then left alone for spontaneous delivery. In former days it was performed in order to deliver rapidly for *eclampsia* and other distressing conditions of the mother. It is recognised now, however, that rapid delivery is the worst possible treatment for eclampsia and for any other condition in which such shock would be dangerous. Internal version to produce a breech presentation has been used by Potter of Buffalo for delivering the great majority of all fœtuses presenting by the vertex. He claims that it abolishes the long delay of the second stage, and so saves the mother pain and fatigue. He also claims that his results compare favourably with normal labour. By long practice Potter himself has become extraordinarily adept at the manœuvre of delivery by version, as the writer can testify by having seen him at work, but it is unlikely that his method will ever be adopted on a large scale.

METHOD

The woman is anæsthetised and prepared as already described, and the gloved hand is passed slowly up through the cervix, displacing the head or shoulder to the side on which lies the back. The operator may use either hand according to the side of the child's back.

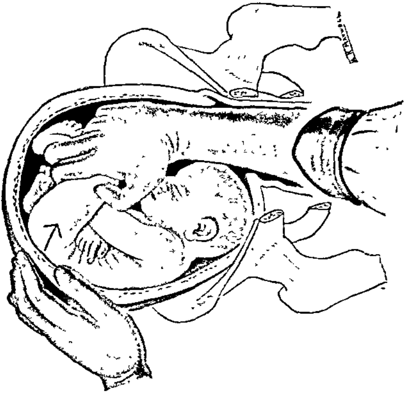

Fig. 2124.—INTERNAL VERSION. THE RIGHT HAND IS PASSED UP INTO THE UTERUS TO GRASP THE NEAREST KNEE, WHILE THE LEFT HAND PRESSES THE BREECH TOWARDS THE INTERNAL HAND

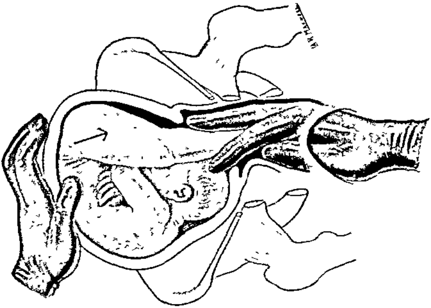

Fig. 2125.—INTERNAL VERSION. THE GRIP OF THE FOOT AND PRESSURE ON THE BREECH AT THE FUNDUS.

If the back is to the left, use the left hand. The passage of the hand into the uterus is liable to stimulate contractions, which render it necessary to keep the hand still until the pain has disappeared. The anæsthetic may have to be deepened if the uterus is irritable. In any case, the hand is manœuvring in a confined space, and, if there is any difficulty, the operator may find that it becomes almost paralysed with fatigue. The object is to grasp a knee (fig. 2124) and then the foot, which is gently pulled down towards the os between the pains. In shoulder presentations it is important to grasp the lower knee or foot

Fig 2126.—The foot has been grasped and pulled down through the os. Meanwhile the external hand pushes up the head from the iliac fossa to the fundus

in order to ensure rotation of the back to the mother's front. Meanwhile the other hand is pressing the breech down (fig. 2125) or trying to move the head up as the internal hand pulls the leg down (fig. 2126). When the leg has been brought through the os, the version is complete, and in nearly all cases it is better to leave the breech within the pelvic cavity for spontaneous delivery. If, however, the fœtus is small or shocked, or the mother exhausted, it is wise to extract the child slowly at once.

Contra-Indications. The outstanding danger of internal version is rupture of the lower segment in cases where the uterus has been for many hours in strong contraction. By the time the state of tonic

contraction has become established the lower segment is stretched and thin and unable to bear any increased tension. No amount of relaxation of the tonically contracted fundus by anæsthesia or other means will alter the attenuated condition of the lower segment. It is a semi-paralytic condition and is incapable of recovery for many hours. Herein lies the failure of adrenalin to relax the uterine condition. While it may inhibit the fundal contraction, though never sufficiently when it has become tonic, the lower segment is incapable of recovering its thickness and normal resistance.

If the uterus is merely "irritable" but not in a state of tonic contraction, the lower segment may not be dangerously thin. Sufficient anæsthesia is capable of abolishing the irritability and rendering the operation safe, but in all cases of labour which has been prolonged there is a risk of the lower segment having become dangerously thin. Internal version should never be attempted for any case in which Bandl's ring—the groove between the thick upper segment and the thin lower segment—can be felt or seen.

CHAPTER III

Forceps

Varieties.

There are four types of forceps in use to-day :

1. The *short straight forceps* is the direct representative of the original instrument invented by Chamberlin in 1600. It has no shank and no pelvic curve, and is therefore smaller and lighter than the long curved forceps. It is seldom used now, but there is no doubt that it is a useful and comparatively safe instrument for extracting the head when it is lying on the perineum.

2. The *long straight forceps* is the instrument most commonly used to-day. It differs from the short variety by the interposition of a shank 2½ inches long between the handle and the blade, and by having a pelvic curve of the blades. It is this curve which adapts the instrument to fit the birth canal and so allows it to be applied to the head as it lies high up in the pelvic cavity.

3. *Axis-traction forceps* (fig. 2127) are similar to the long curved forceps but have in addition an arrangement of traction rods by which the head can be pulled down

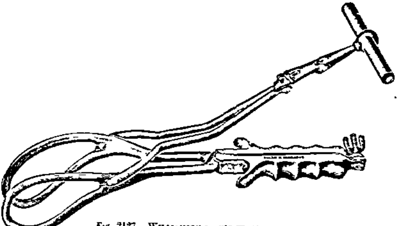

Fig 2127.—Williamson's axis-traction forceps.

in the direction of the birth canal at whatever level the head may be lying. It is designed for use when the head is high or in the brim, in order that traction may be made downwards and backwards. If, when the head is high, the ordinary forceps are used the direction of traction will direct the head not only downwards, but also forwards against the symphysis, whereby much of the mechanical advantage of the traction is lost. Axis-traction forceps are used less now than formerly in view of the tendency to use the forceps only when the head is low in the cavity, but though they have been condemned as dangerous, there are cases where forceps must be applied when the head is at or just through the brim. In such cases, only by the use of traction rods can the head be pulled in the direction of the birth canal, that is, downwards and backwards.

4. *Kielland's forceps is a special instrument differing considerably from the ordinary types.* A description of its details and use will be found on page 3880.

CONSTRUCTION OF THE FORCEPS

The essential features of ordinary long curved forceps are :

(*a*) The instrument should be entirely made of metal, and sufficiently firm to be almost completely rigid without any risk of bending under moderate strain. *There should be a little "give" at the tips of the blades. If the instrument is* too light the blades or shank may bend. On the other hand, it should not be too heavy, as, for example, Tarnier's forceps. This is a valuable instrument for a really difficult extraction, but for ordinary work it is dangerously heavy.

(*b*) The measurements of the various parts of the instrument are more or less standard. The handles should be 5 inches long, the shanks 2½ inches long, the distance between the tips of the blades 1 inch, and the distance between the widest *part of the blades* 3⅜ *inches.*

(*c*) The instrument should be fitted with detachable, axis-traction rods. If the axis-traction mechanism is not required, the forceps can readily be used in the ordinary manner for delivery of the head when lying low in the pelvic cavity. The rods are jointed between their attachment and the traction handle in such a way as to allow free movements of the blades.

There are several different varieties of forceps on the market. In my *opinion Williamson's is the best instrument.* The advantages of these forceps over others are that the traction-rod mechanism is simple and derives its pull from the base of the fenestræ of the blades and not from the handle (as in Neville's and Stack's forceps), also the screw which locks the handles is placed at the end of the handles and so is out of the way of the perineum. In some models this screw is close up to the shank, and when the instrument is applied to a high head the screw may injure the perineum.

INDICATIONS FOR THE USE OF FORCEPS

There have been few topics more debated than the use of forceps, not only the question of the immediate indication, but also, indirectly, the part played by the use of forceps in the production of sepsis and injuries. While it may be an instrument of the utmost value to both mother and child, yet it can, by injudicious use, be made a lethal weapon.

There can be only one general indication for the use of forceps, i.e. insufficient uterine force to expel the child within a reasonable time—by "reasonable" I mean safe for both mother and child. When discussing this subject the books usually describe the list of detailed indications for the use of forceps. I propose to present the subject more from the clinical point of view, describing the clinical types for which the use of forceps is good treatment.

1. *Uterine Inertia.* There are very many labours, often in primigravidæ, in which the contractions and progress have been normal, even rapid during the first stage, and also during the second stage until

the head rests on the perineum and levatores ani muscles. At this stage, when the scalp can be seen between the labia during the pains, further progress seems to stop, at least, a disproportionate amount of time passes before the head descends and stretches the perineum; or, the stand-still may come a little later when the perineum has already begun to distend. In view of the previously rapid progress, the attendant hopes that a little more time with the head at the outlet may be sufficient to allow the woman to deliver herself, but this hope is disappointed by the gradual weakening and failure of the contractions. Particularly is this so if the patient is a primigravida. If no assistance is given, the "pains" pass off entirely, but after a rest of an hour or two they may reappear and ultimately expel the child. But such a method of delivery causes a great deal of unnecessary pain and exhaustion, in addition to a risk of losing the child. Such cases, therefore, are eminently suitable for delivery by forceps at the moment when the weakening pains and failure to advance further make it clear that spontaneous delivery cannot be expected for some long time.

The use of chloroform or other anæsthesia at the end of the second stage is now widely extended to include not only middle-class practice, but also that of many hospitals. A failure of the uterus just at the time when its full strength is required to drive the head through the resistant vaginal orifice is a frequent result of anæsthesia, and therefore forceps are required in the majority of cases

If the instrument is applied cleanly and carefully to a fully rotated head, and extraction is performed gently and slowly, there is a minimum of danger, and great benefit to both mother and child.

2. *Labour with the occiput posterior* If spontaneous rotation of the occiput fails, labour is usually greatly delayed and may be obstructed. Occasionally the head may be delivered quite unexpectedly in the "face-to-pubes" position, but only if the head is flexed, despite the position, or if the child is unusually small. Generally the unrotated head requires the assistance of manual rotation. When this has been done, provided the os is fully dilated, it is the usual custom to apply forceps and deliver.

For multiparæ, and where the os is fully dilated and the head is in the cavity, it is good practice, for in all probability the woman has had a long labour, of which the latter part has been particularly exhausting and painful. A further advantage of immediate application of forceps and subsequent delivery is that, unless it has been possible to rotate the body completely, the head is sure to slip back into the posterior position as soon as the hand's grip has been removed.

There are cases, however, where forceps should not be applied after rotating the head. If both the head and body have been satisfactorily rotated to the front and the os is not sufficiently dilated, no attempt should be made to apply forceps at once.

The common clinical course of these cases is as follows: The membranes rupture before or early in labour, and, from the beginning, the pains are feeble. Many hours, even days, may elapse before the os is half dilated, and an examination made to discover the cause of delay finds an unrotated occipito-posterior position. It is believed that the extended position restrains descent of the head on to the cervix, and thus prevents the natural stimulus for the maintenance of contractions. As drug treatment (morphia, chloral, etc.) has been used without success, it is well to anæsthetise the patient, dilate the cervix sufficiently to insert the hand, and rotate the head and body. The mere change of position of the occiput from posterior to anterior will ensure the flexion of the head. But after rotating the head through the os, which only just admits the hand, it would be dangerous to apply forceps and deliver at once despite the fact that the woman has been in labour some days, unless her condition urgently demand delivery. The rotation of the head, accompanied by the inevitable flexion, is often associated with an improvement in the pains and a fairly quick dilatation. As soon as dilatation is complete, forceps should be applied immediately to save the exhausted mother the final ordeal of unaided expulsion.

The third variety of the posterior position is that for which manual rotation fails—the so-called persistent occipito-posterior. If the child is alive an effort must be made to extract it by forceps after making an effort to flex the head. Sometimes a large pelvis will allow a small head to be dragged through in the uncorrected position, but in many cases no progress can be made. As soon as the child is dead the head should be perforated.

3. *Delay due to contracted pelvis.* The common type is due either to the arrest of the head in the cavity of a pelvis which is generally contracted, or to difficulty caused by the head of a large child in a pelvis which has no pelvic reserve. The clinical features of the labour are those of a uterus tiring after a great effort to drive the head through a small cavity. The woman's general condition will also be that of exhaustion. Vaginal examination will find the signs of pressure. The head will be jammed, with a large caput and strongly overriding sutures, there will be an œdematous anterior lip of the cervix, prolapsed beneath the head, and possibly some œdema of the labia. The child's

heart may be showing signs of distress, or, if the uterus has been contracting very strongly for some hours, the child may be dead. There is no question of Cæsarean section, for in such a case there is no hope of delivering a live child, even though its heart is beating before the operation, and there is also great danger to the mother.

Therefore forceps should be applied and delivery attempted. Axis-traction rods will help, and if the traction is reinforced by a strong thrust of the uterine contractions, there is some chance of delivering a live baby. If during the attempt the fœtal heart ceases to beat, the head should be perforated.

The other variety of contracted pelvis—the flat pelvis—may offer a more difficult problem. Here the head is held up either above or in the brim. Most obstetricians agree that in the former case forceps have no place in the treatment, but if the head is wedged in the brim axis-traction forceps may be used, provided a considerable time has elapsed for full moulding of the head, as proved by the overriding sutures. If there is no superimposed general contraction, the cavity will be normal and the subsequent passage of the head will be easy. Some authorities deprecate the use of forceps in all cases in which the head has not passed the promontory, but if it has descended sufficiently to become well engaged in the brim, the possibility exists that some reinforcement of uterine contractions by artificial help will be just enough to enable the head to pass the brim.

A nice judgment is required to make a decision. If forceps fail, the danger of a subsequent lower segment Cæsarean section is greatly increased, and the child will probably have been severely injured. Chief attention should be paid to the amount of descent through the brim, or how far it is likely that the major diameter is actually in the grip of the promontory and symphysis. If it is still above this strait, forceps offer little hope. Another point is the size of the pelvic cavity and outlet—usually normal in the milder degrees of flat pelvis. If the child is nearly dead the attempt is useless.

In general we may say that it is only exceptionally justifiable to apply forceps when the head is still engaged in the brim, but that there are occasional cases where the operation is worth while.

4. *Delay before full dilatation of the os.* Prolonged delay in the first stage of labour can be a very troublesome and even dangerous complication. The large majority of cases will ultimately complete dilatation with no more treatment than sedative drugs and patience; but of all cases of labour there are about 1 in 60 primigravidæ and 1 in 300 multiparæ who suffer from delay greater than 48 hours, and sufficient

to produce symptoms of exhaustion. After some days of labour the situation may become anxious, and the inevitable question arises—can forceps be used without further waiting? While it is acknowledged to be the worst practice to apply forceps and deliver through the undilated os, yet there are occasionally cases of delay in the first stage which may be more safely delivered by forceps than left for still more hours and days of labour. The signs and indications which may be regarded as justifying the use of forceps before dilatation are as follows:

(*a*) The mother and child should be showing definite signs of exhaustion. Labour may last for days without either suffering from fatigue, but usually after so long a time has passed, especially if the membranes ruptured early in labour, there will be some indications of distress. If both parties are perfectly well, the woman should be allowed to wait and, emphatically, forceps must not be used to save time. But if the general condition of either begins to give anxiety there must naturally be some thought as to how soon delivery can be effected.

(*b*) The os must be *dilatable.* During labour the lapse of time will be associated not only with the dilatation of the os, but also with *softening.* While twelve hours, even if feeble pains have been present, may not be followed by any appreciable increase of dilatation, yet it is probable that the os will be softer and more dilatable than at the beginning of the given twelve hours. It is not uncommon, therefore, to find that, after a woman has been in labour for many hours or days, though the os fails to become fully dilated, yet it is easily dilatable by the hand under anæsthesia.

If it is found that the os can be easily dilated by the hand—and it is often surprising to find how easily this can be done after hours of contractions have failed—and other conditions are favourable, forceps may be applied. Before any traction is made, the head is held in position while the fingers of the left hand complete the dilatation by pushing the rim of the os up over the head. Push it up first behind, then at the sides, and finally at the anterior lip. When the edge of the os can no longer be felt, the head can be pulled and extracted in the usual way.

If forceps are applied before full dilatation, it is always most important to push the whole of the cervix above the head rather than attempt to pull the head through it. If this is done, even gently and slowly, serious tears are inevitable, but if the os is pushed up, it may be possible to deliver without any but the smallest laceration.

(c) Any maternal condition which renders further delay during the second stage a source of exhaustion or danger. The best example is

strong probability of successful passage of the head, but it is usually the doubtful cases which cause most anxiety. The chief points for consideration are as follows:

(a) Continued and steady progress, even if slow, usually indicates that an additional force applied through the forceps will so assist the force of the uterus that successful delivery will be accomplished.

(b) An anterior occiput, completely flexed, affords a hope of delivery, but it is quite certain that the opposite conditions of posterior occiput and absence of flexion will effectually prevent it in a borderland case of pelvic contraction.

(c) If, during a pain, the head can be felt to descend, or if, between the contractions, the head can be pushed up by the finger, an attempt to deliver by forceps may be made, as these movements indicate that so far there is not complete impaction. But if the head cannot be made to move, and if, in addition, the maximum moulding has already occurred, as shown by great overriding of the bones (should it be possible to feel the sutures), there is little or no hope of extraction.

Great œdema of the scalp (caput succedaneum), of the cervix, and even of the vulva, nearly always indicates impaction. The presence of much œdema means that for some hours, at least, the uterus has been contracting strongly, and if, in spite of this, progress has come to a standstill, there is little chance of success with forceps, but if the caput is small and there is no œdema of the cervix, then the contractions have never been strong, and failure to progress may be less the result of mechanical disproportion than of failure of expulsive force. Forceps in this case may succeed.

5. Forceps should never be applied in the presence of *tonic contraction* of the uterus, because this condition invariably indicates insuperable obstruction and an already dead child.

6. In all the books and teaching, emphasis is laid upon the danger of extracting the fœtus in the *absence of pains*. This injunction refers to the state of true uterine exhaustion, or so-called secondary uterine inertia. It is a state which follows prolonged and hard contraction, due to some obstruction either relative or absolute. The danger lies in the complete inability of the uterus to contract after delivery. Atonic and probably fatal post-partum hæmorrhage is then inevitable. A much commoner clinical condition of absence of pains is primary inertia which may first occur when the head has come down to the perineum. In this case there is no actual exhaustion nor total incapacity of the uterine muscle to contract, but only a reflex inhibition, due to no certainly known cause. The introduction of forceps and extraction

removes the inhibition, and is followed by contractions sufficient to prevent post-partum hæmorrhage. Indeed, it is a rare event for hæmorrhage to follow the labour of primary inertia.

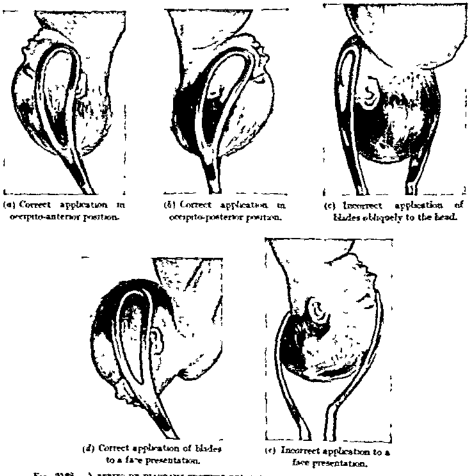
When the head has descended far enough for the application of forceps, there may be considerable doubt whether it is safe to deliver when the uterus is apparently not contracting. There is a natural fear of delivery in the absence of pains, and yet the tired state of the mother or child may be a strong indication to terminate labour. In the state of primary inertia the uterus is always potentially able to contract, and will do as the child is delivered; but in uterine exhaustion the muscle is clinically paralysed and cannot contract. Signs of pressure, such as a large caput, œdema of the anterior lip of the cervix, and extreme moulding, will be present. Some cause of obstruction, for example, occipito-posterior or contracted pelvis, will probably be obvious. Further, the child will be distressed or even dead, and a hand held on the uterus for some minutes will feel it entirely and continuously soft, without the slightest trace of hardening. In primary inertia there are no signs of strong pressure, the uterus has been sluggish during the whole labour, the child is well, and though there are apparently no pains, yet the hand will feel slight rhythmical hardening which indicates that the uterus is potentially able to contract. In the latter case, forceps may be applied with perfect safety.

METHODS OF APPLYING FORCEPS

The patient must be anæsthetised and placed either on her back or left side. The vulva is shaved, unless this has been done already, and cleansed with a suitable antiseptic lotion such as dettol. A catheter is passed before any internal examination is made. It is most important that the bladder should be emptied before delivery.

After all the preliminaries are completed the left hand is passed slowly and gently into the vagina. In a primigravida there may be difficulty in inserting the hand without tearing the perineum. Should the introitus be tight, special care must be taken to pass the knuckles slowly in order to dilate rather than tear the perineum. This, and gentleness expended in passing the hand, will, by stretching the resistant tissues, do much to facilitate delivery and prevent a deep tear as the head emerges. When the hand has at last been introduced it is well to spend a minute or two in "ironing out" the posterior vaginal wall with the back of the hand. This should be done slowly and carefully by pulling the left hand down on the posterior vaginal wall and perineum so as to secure as much stretching as possible. Before the blade of the

forceps is passed the left hand must find out certain details. Firstly, whether the os is fully dilated and has slipped up above the head. It is also essential to confirm the exact position of the head. Even though a first or second vertex position has been known to exist at the beginning of labour, it is wise to examine at this juncture, just before the application of the forceps blades, to be quite sure that the head is not lying



(a) Correct application in occipito-anterior position.

(b) Correct application in occipito-posterior position.

(c) Incorrect application of blades obliquely to the head.

(d) Correct application of blades to a face presentation.

(e) Incorrect application to a face presentation.

Fig. 2128.—A series of diagrams showing relations of the blades to the child's head, in the various presentations of anterior, posterior vertex, and face.
(*From Eden and Holland's "Manual of Midwifery"*)

in the occipito-posterior position. Again, either the sagittal axis of the head may be lying unrotated in the oblique diameter of the pelvis, or internal rotation may have been completed before the head reaches the perineum. Should the blades be applied strictly in relation to the lateral walls of the pelvis when the head has not yet rotated, the grip will be partly over the face, and may cause serious bruising or even damage to the orbit. Not only may the head or face be injured, but an oblique grip of the head is liable to allow the forceps to slip under even

gentle traction (fig. 2128). A further disadvantage of the oblique grip is that the head will almost certainly be extended by traction. This movement will throw a larger diameter across the pelvis and will thus add to the difficulty of extraction. It is most important, therefore, to grasp the head accurately in the transverse diameter. There is less chance of injury, slipping of the blades, or extension of the head. If the head is found in the oblique diameter, the blades must be applied asymmetrically in relation to the pelvis, so as to grip the head squarely. As the occiput rotates from the oblique to the antero-posterior diameter, the forceps will also pass round the eighth of a circle, and so come to lie in the transverse diameter of the cavity, and later, in the outlet. Despite the pelvic curve of the instrument, no harm will be done to the soft tissues by rotation of the blades through this small arc.

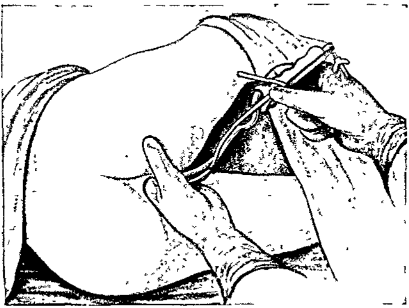


Fig 2129.—THE APPLICATION OF THE LOWER OR LEFT BLADE
(*From "Queen Charlotte's Text Book of Obstetrics"*)

Introduction of the left (or lower) blade. We will assume that the patient is lying on her left side. The operator's left hand has been carefully introduced so as not to tear the perineum, it has spent a few minutes in gently stretching (or "ironing out") the posterior vaginal wall and perineum, and it has ascertained that the cervix has slipped above the head, and the exact position of the head in reference to the pelvis. The hand is laid flat against the side of the head, between it and the cervix. The right hand now takes the handle of the left or lower blade and passes the blade into the vagina with the tip closely applied to the palm of the internal hand (fig. 2129). The handle is at first elevated,

but as the blade passes up the vagina it is gradually lowered until the whole blade is horizontal. The blade slides in until it has found its position, snugly applied to the side of the head. As I have already explained, it will probably not lie in the transverse diameter of the pelvis because the head still occupies its oblique diameter. The internal hand is then passed round the pelvis to find the other lateral surface of the head, while at the same time the left elbow is used to steady the position of the blade just inserted. In the same way the right (or upper) blade is passed, by holding the handle depressed, and gradually lifting it as the blade slides into position against the side of the head. If the blades make a "square" grip of the head, the handles will almost drop together

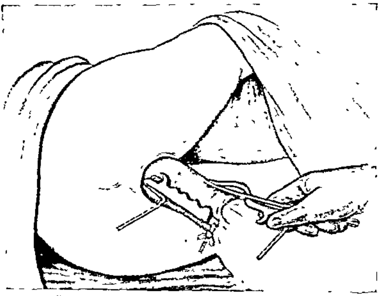

Fig. 2130—The application of the upper or right blade.
(*From "Queen Charlotte's Text Book of Obstetrics."*)

and can easily be locked without any force (fig. 2130). Ready locking of the blades is a sure sign that the head is grasped by its transverse diameter.

Before any traction is made, the left hand makes a final examination to be sure that no maternal tissues, or the cord, are gripped by the instrument.

Traction. A preliminary pull should be made while the left hand is in the vagina in order to note that there is no tendency for the blades to slip. The hand is then removed, and the handles held in the right hand with two fingers over the shoulders at the junction of the handle and shanks (fig. 2131).

There are several details in the process of traction which must be described, because it is due to faults at this stage of the operation that

injuries can occur. The first essential is to pull only *with* the pains. There may be no obvious contractions since the woman is anæsthetised, but often the act of pulling stimulates a contraction, or if the uterus appears to be completely flaccid, a few minutes of delay will usually allow a small but definite hardening of the uterine wall to be felt. The importance of pulling during the contractions is that the thrust of the uterus, even during a feeble pain, adds considerably to the force exerted by the forceps. It is often noticed that while no appreciable descent can be made by pulling while the uterus is flaccid, yet as soon as it hardens traction on the head at once becomes effective.

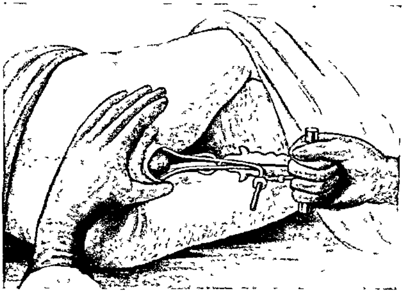

Fig. 2131 —Traction on the forceps is being directed forward as the head is distending the perineum

(*From* "*Queen Charlotte's Text Book of Obstetrics.*")

The amount of force exerted by the operator is important. In the ordinary case of "low forceps", no more force is necessary than can be exerted by the wrists and elbows, but in cases of disproportion or incomplete flexion it is usually necessary to pull firmly from the shoulder. Stronger traction than this is often employed, but is dangerous, both to the child's head and the birth canal. As the head is beginning to distend the perineum, *episiotomy* will always reduce the amount of traction required in a primigravida, and will also often save a rupture of the perineal tissues.

The time required for forceps delivery varies according to the circumstances of the case. Where the head is just lying above the perineum, it may be lifted out within two or three minutes, but if it is partially impacted high up in the cavity, traction may have to be exerted for half an hour or more. So long as the operator feels that each pull

produces some degree of descent, even though quite small, there is justification for continuing, but if with the strongest permissible force there is no sensation of descent after 15 or 20 minutes, further efforts are usually hopeless. The child will probably be dead, and, if so, a perforator should be passed into the head between the shanks of the forceps. The reduction of the size of the head allowed by the escape of brain substance will nearly always enable the extraction to be finished without great difficulty.

Occipito-posterior presentations. The ideal treatment is to rotate the head and deliver by forceps, but occasionally it is impossible to rotate the head by hand. and the question arises of attempting to rotate it by the forceps. Many obstetricians think this is a dangerous practice because, where manual rotation has failed. the force necessary to be exerted through the forceps is so great as to be dangerous. A better practice is to attempt to pull the head down with a gentle rotary movement applied during the traction. In this way, the rotation that usually accompanies descent is encouraged by the extra assistance given by the forceps, and gradually the head may be brought round. As the head rotates and the blades thus come to lie asymmetrically in relation to the pelvis they should be removed and reapplied.

Face presentation. A common trouble in face labour is delay due to inertia. Where the conditions are suitable, forceps extraction is good treatment and offers no special difficulty. As the comparatively long submento-vertical diameter must pass under the perineum, an episiotomy is particularly useful to avoid perineal tears.

The after-coming head. Some obstetricians are accustomed to deliver the after-coming head by forceps, but most of us extract it by one of the familiar manœuvres. If there is impaction sufficient to prevent delivery by the jaw-traction method, forceps may be successful, but by the time forceps are applied, too much time has already been absorbed in attempts to deliver by hand. During the application of the blades the child's body must be pulled well forward towards the symphysis.

KIELLAND'S FORCEPS

The following description of these forceps was given to me by Dr. Kielland on the occasion of his recent visit to Queen Charlotte's Hospital.

The instrument was first introduced by him in 1915, but even now it has not been widely used in England. It is more difficult to apply, but nevertheless there are definite indications for its use in selected cases.

Kielland's forceps differ from all other types of modern forceps in the following respects (fig. 2132):

1. The pelvic curve is considerably reduced. The blade therefore resembles that of the old straight forceps, except that it is inclined a little posteriorly on the shank.
2. There is no alteration in the radius of the cephalic curve. The tips of the blades are separated by 2·2 cms., and the maximum separation is 8 cms.
3. Apart from the absence of pelvic curve, the most striking difference from orthodox forceps is in the lock. There is no actual lock, but a slot on one shank, *by which the shanks and handles merely slide one along the other* in a longitudinal direction. This arrangement thus allows each blade to grip the head at a different vertical level.
4. The shanks are considerably longer than those of ordinary forceps, and they are straight from the handle to the blade. The part immediately below the fenestrated portion is light, thin and rounded. The whole instrument is lighter and more slender than any other form of forceps.

The object of the forceps is to grasp the head symmetrically, no matter how it lies in the pelvis. The long diameter of the head usually lies *in the transverse diameter of the brim and cavity before the os is*

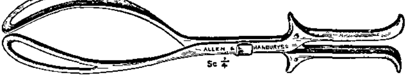

Fig. 2132.—Kielland's forceps

fully dilated, and frequently after the rupture of the membranes it still lies in this diameter, or, in the case of the occipito-posterior positions, it will lie in the oblique diameter. It is often only towards the end of the second stage that the sagittal diameter rotates from the transverse through the oblique to the antero-posterior diameter. It therefore follows that the grip of the head by the ordinary forceps, applied conventionally with regard to symmetry with the pelvis, will often grip the head askew. One blade may even grasp the forehead and the other the occiput, but Kielland maintains that his forceps can grasp the head however it lies in the pelvis, so that both blades are laterally placed on the skull. Further, as the head rotates with downward traction, the forceps can follow this movement because they have no pelvic curve. He also states that the application of the ordinary forceps in unrotated cases is liable to push the head into the occipito-posterior position or to extend it. It is not the high position of the head which renders the operation dangerous and difficult, but the wrong application of the blades in relation to the transverse diameter of the fœtal head. By eliminating this difficulty he claims that his instrument may be used without danger for "high forceps" extractions.

The following points should be observed in applying Kielland's forceps:

1. With the patient anæsthetised and lying on her back in the lithotomy position, a careful examination is made by the whole hand to find exactly how the sagittal diameter is placed in reference to the pelvis. It is most important that there should be no doubt on this point.

2. Take the forceps, articulate the blades and hold them at the vulva exactly as they must be applied to the head in the position which has just been ascertained. The concavity of the slight pelvic curve

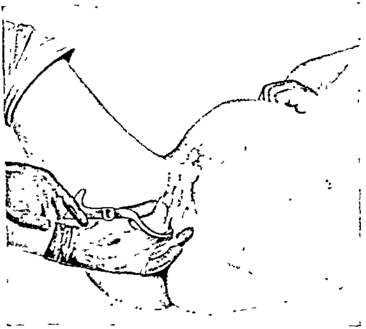

Fig. 2133.—Introduction of the anterior blade, which is passed in front of the head. (See also *Fig.* 2134.)
(*From Bourne and Williams' "Recent Advances in Obstetrics and Gynæcology"*)

should be directed towards the occiput, so that when the occiput has rotated to the front the forceps will correspond to the curve of the sacrum.

3. Next, take hold of the anterior blade by the fenestrated portion (not the handle) and lay the other blade aside. Then transfer the grasp to the handle.

4. Introduce the hand into the vagina and pass two fingers between the fœtal head and the symphysis. Pass the anterior blade, guided by the left hand, into the vagina with its *concavity towards the symphysis*, until its tip touches the head (fig. 2133). Then lower the handle slightly and pass the blade between the cervix and head until the middle of its concavity is behind the symphysis.

5. Rotate the handle slowly through 180° on its long axis, towards the side on which the button is situated on the handle. The blade will now lie snugly over the side of the fœtal skull (figs. 2134 and 2135).

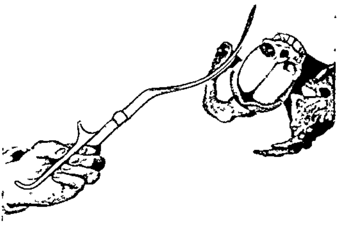

Fig 2134.—DIAGRAMMATIC REPRESENTATION OF THE MANŒUVRE SHOWN IN *Fig.* 2133.
(*From Bourne and Williams' "Recent Advances in Obstetrics and Gynæcology"*)

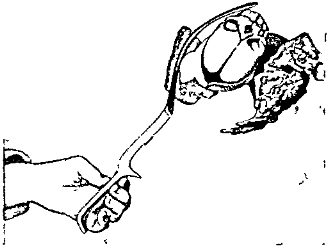

Fig 2135.—SHOWS THE POSITION OF THE BLADE AFTER IT HAS BEEN ROTATED FROM THE POSITION SHOWN IN *Fig.* 2134.
(*From Bourne and Williams' "Recent Advances in Obstetrics and Gynæcology"*)

6. The posterior blade is introduced as follows: "Pass two fingers into the vagina between the posterior cervical lip and head; pass the second blade posteriorly *on the side where the lock will approximate to that of the first blade,* and introduce it gently to the side or in front of the promontory. The blade meets no resistance unless the pelvis is contracted or the head impacted low down. In that event do not use force, but gently manipulate it by lowering or lifting its handle." (Bourne and Williams.)

7. After articulating the blades, pull gently. The blades will slide a little on one another, so that one will lie at a slightly higher level than the other. This is due to either blade adjusting itself to the different

levels of the sides of the head relative to the pelvis. The forceps lie in the antero-posterior diameter of the pelvis, and have gripped the head symmetrically in its transverse bi-parietal diameter.

8. Draw the head downwards and backwards, allowing the forceps to follow the rotation of the head. As it descends still lower, assist the rotation already indicated by an active movement of the handles. Towards the outlet the occiput will come to lie to the front, but during extraction take care not to pull too much in a forward direction, as with ordinary forceps.

9. In the unrotated occipito-posterior position the blades are inserted as before, except that in order to grasp the head squarely they will lie first asymmetrically in relation to the antero-posterior diameter of the pelvis. After application, rotate the head before applying traction, and then draw it down.

Kielland's forceps should not be used:

1. In a contracted pelvis where the head remains above the brim.

2. When the lower uterine segment is stretched and a retraction ring is present.

It is important to have practised the use of the instrument on a manikin, and to be sure of the diagnosis of the lie of the fœtal head.

The advantages of Kielland's forceps are:

1. The grasping of the head by its bi-parietal diameter, as a consequence of which the forceps cannot slip off the head.

2. Because the blades fit the head closely, this instrument is safe for rotation.

3. The blades are applied to that part of the child's head which can best endure pressure, namely the cheeks and the underlying bones. There is no pressure on the orbit, brow, nose, neck, or facial nerve as so often occurs when the ordinary forceps are applied to an unrotated head.

4. The head is not displaced by the introduction of the blades; this can be of importance when the pelvis is somewhat contracted.

5. As less traction is necessary for delivery than with ordinary forceps there is less risk of maternal injuries. (Bourne and Williams' *Recent Advances in Obstetrics and Gynæcology*.)

CHAPTER IV

Destructive Operations

CRANIOTOMY

The operation of craniotomy is performed to reduce the size of the fœtal head in certain cases of difficult delivery. It consists of two or three procedures: 1. Perforation; 2. Extraction; 3. Cranioclasm.

1. *Perforation.*

It is necessary to perforate the skull in order to allow the escape of brain substance, after which the cranial bones are able to collapse. For this purpose an instrument called a perforator is used. Of the various patterns on the market the best is Oldham's (fig. 2136). It

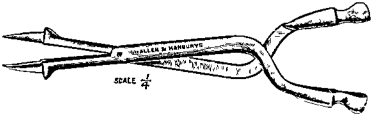

Fig. 2136.—Oldham's perforator.

consists of two blades articulating by a screw lock. Each blade has a handle, a long shank, and a sharp-pointed member an inch long, with a moderately sharp outer cutting edge. The shank carries a shoulder at the base of the perforating member, which is important in so far as it prevents the whole length of the instrument being pushed suddenly into the skull.

Indications. For all cases of difficult delivery due to contracted pelvis or disproportion between the size of head and pelvis, or impaction of the head in the posterior face, or brow positions, when the child is dead or actually moribund, and after reasonable efforts to deliver by forceps have failed, perforation may be performed. If the child is dead it is not necessary that labour should be completely obstructed —perforation should be carried out if unnecessarily hard traction by forceps is required, even if some progress is being made. Less trauma is likely to arise from perforation followed by extraction than from continuation of fruitless attempts at rotation of an impacted occipito-posterior, or strong efforts to deliver an impacted after-coming head.

It is necessary that the os should be fully dilated before extraction is attempted, but perforation alone may be done when the os is not more than half dilated. In some cases of very resistant dilatation it may be useful to perforate the head and fix a cranioclast thereto. A weight attached to the cranioclast will then produce a constant tractive force which will often overcome rigidity of the os. In general, however, the os is fully dilated by the time the fœtus is dead. It is rare that the os is too small for the use of the perforator.

Extreme degrees of contracted pelvis are unusual in this country, but in some parts of the world they are not so uncommon. Before attempting delivery by craniotomy it is necessary to be sure that the pelvis is not so greatly contracted as to render extraction impossible. The writer's experience contains one such instance. After prolonged efforts to break up the head and draw it through the brim (true conjugate of $2\frac{1}{2}$ inches or less), it was found impossible to extract the body, and Cæsarean section was performed. The patient survived, but the abdominal wound sloughed. The question of perforation of a live child is often discussed, but it seldom arises in practice. By the time that efforts to deliver by forceps have been given a fair trial in cases of obstruction, the child is usually moribund or dead. It is dead in all cases of obstructed labour that have reached the stage of tonic contraction, and in nearly all cases of "failed forceps" the shock to the child is such that, though not actually dead, the chance of survival after Cæsarean section delivery is very slender.

In cases where the child is in good condition but impossible to deliver alive by the vagina, the lower segment Cæsarean section offers a comparatively safe method, even after the membranes have been ruptured some hours and vaginal examinations have been made. Finally, obstructing hydrocephalus should always be perforated.

Operation. The patient is anæsthetised and placed on her back in the lithotomy position. Most careful disinfection of the vulva and vagina is made by dettol or iodine in glycerine. This is necessary because of the probable presence of infection following a long period of labour and previous manipulations.

The left hand is passed into the vagina until the head can be explored. The perforator is taken in the right hand and passed along the left hand so as to protect the maternal parts from damage by the blades. The points of the blades are pressed firmly against the head at right angles to the surface in order to avoid slipping, and if possible over bone and not over a suture (fig. 2137). In the case of a face presentation the instrument should be passed into the orbit.

Slight pressure is used at first to pierce the scalp. After the points have perforated the scalp there is little danger of their slipping off the head, and then firmer pressure is made to pierce the bone. This follows in a few moments and allows the blades to sink into the skull up to the shoulder of the shank. The handles are closed, by which action the blades are opened and the bone broken ; they are then opened, rotated through a right angle, and closed again (fig. 2138). This double opening and

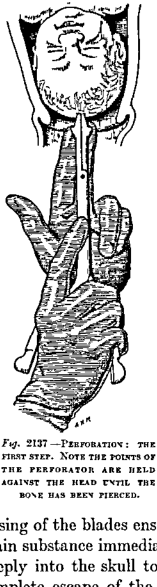

Fig. 2137.—PERFORATION: THE FIRST STEP. NOTE THE POINTS OF THE PERFORATOR ARE HELD AGAINST THE HEAD UNTIL THE BONE HAS BEEN PIERCED.

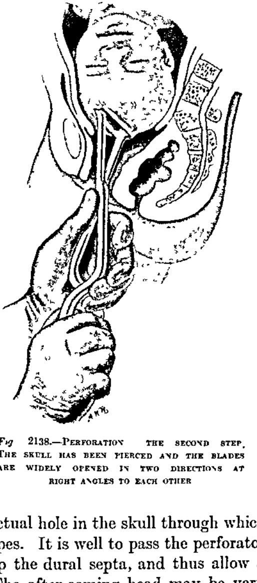

Fig 2138.—PERFORATION THE SECOND STEP. THE SKULL HAS BEEN PIERCED AND THE BLADES ARE WIDELY OPENED IN TWO DIRECTIONS AT RIGHT ANGLES TO EACH OTHER

closing of the blades ensures an actual hole in the skull through which brain substance immediately escapes. It is well to pass the perforator deeply into the skull to break up the dural septa, and thus allow a complete escape of the brain. The after-coming head may be very difficult to reach if it is held up at the brim. Strong traction by an assistant is made on the legs downwards and backwards, in order to bring the occiput as low down as possible behind the symphysis. It is palpated by the fingers of the left hand, and the blades of the perforator are passed, very carefully guarded by the left hand, to reach the

occiput just above the nape of the neck. Pressure must be made with great care as the blades are probably not at right angles to the bone, and are therefore liable to slip if firm pressure is made before the scalp is pierced.

In all cases of minor disproportion or impacted occipito-posterior, the head can usually be delivered easily by forceps after the rigidity of the head has been destroyed by escape of the brain. It is most convenient, therefore, to apply the forceps first, and then to pass the perforator into the skull between the shanks of the forceps. As soon as the dural septa have been broken up, the head will usually descend easily when traction is made by the forceps. The contrast between the firm and " hopeless " resistance offered by the head before perforation, and the ease with which it can be drawn down after perforation, is very striking.

2. *Extraction.*

As I have just described, the fœtus can in the majority of cases be delivered by forceps after perforation alone. If the pelvis is severely contracted it will be necessary either to crush the head or actually to break it up by the cranioclast.

There are two main varieties of the cranioclast, the one (Braxton-Hicks' or White's modification) which is composed of two blades, and

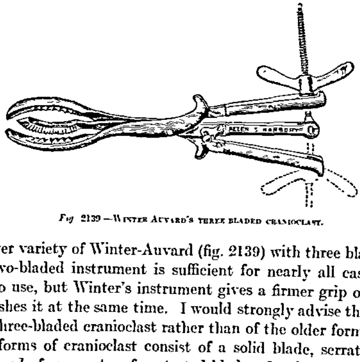

Fig 2139.—Winter Auvard's three bladed cranioclast.

the newer variety of Winter-Auvard (fig. 2139) with three blades. The older two-bladed instrument is sufficient for nearly all cases, and is easier to use, but Winter's instrument gives a firmer grip of the head and crushes it at the same time. I would strongly advise the purchase of the three-bladed cranioclast rather than of the older form.

All forms of cranioclast consist of a solid blade, serrated on one aspect, and of one or two fenestrated blades, deeply serrated on their

concave surfaces. Both the fenestrated blades articulate with the central blade, as shown in the figure. The ends of the handles are provided with a separate member which enables the three blades to be screwed tightly together. It is important that the cranioclast be heavily and strongly made, in order to ensure a very firm, unyielding grip of the head. One of the chief difficulties in the practical use of the instrument is its tendency to slip off the head owing to the imperfect grip and the very strong traction that may be necessary.

The cranioclast as a tractor. For moderate degrees of contracted pelvis it is usually possible to deliver without actual cranioclasm, but by traction alone. A sufficient grip of the head can be obtained by using only the solid and No. 2 blades of Winter's instrument. Having perforated the skull and stirred up the brain, the solid blade is passed through the hole deep into the skull with its serrated convexity directed towards the face. It is not always easy to keep it exactly in position because of the weight of the shank and handle, and therefore an assistant should be present if available. It is important to pass this blade well into the skull, as deeply as possible. The blade No. 2 is then passed over the face, with its concavity directed towards the face. Care must be taken in passing this blade to protect the maternal tissues from injury, by the left hand, and also to pass it far enough up to bring its lock into apposition with that of the solid blade. A firm grip and freedom from slipping are ensured chiefly by passing both blades far enough to grasp the whole face in their concavity (fig. 2140).

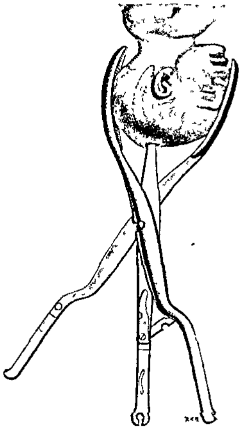

Fig. 2140.—CRANIOTOMY. THE CRANIOCLAST IS APPLIED FOR USE AS AN EXTRACTOR. NOTE THAT ONE BLADE IS PLACED SO AS TO GRASP THE FACE

When the operator is satisfied that the blades are in good position, the handles are screwed together as tightly as possible, and pulled downwards and backwards. After the fruitless struggle to deliver with forceps, the quick and easy descent which follows traction on the cranioclast is surprising and gratifying.

During the first few moments of pulling much more brain tissue escapes, showing the collapse of the skull caused by descent through the pelvic cavity. If there is initial difficulty, or failure to bring the head down, try to rotate the face round to the front or back. This movement produces still more collapse of the head and renders descent possible. It is always advisable to twist the head a little in rotatory movement, to and fro, to ease the grip of the pelvis and force a further collapse of the head.

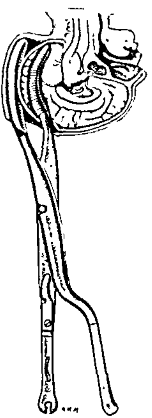

Fig 2141 —Cranioclasm The use of the cranioclast to break up the bones of the cranial vault The external blade is passed beneath the scalp in order to grasp the bone only

Occasionally it may still be very difficult to draw the head down even when the left hand can feel that it is lying quite loosely in the pelvis. This always means that the shoulders are held up, either by the contracted brim or by a contraction ring. This is a serious additional complication, to which we shall refer again later.

Should the pelvis be too small for extraction as we have just described, or if the two-bladed instrument slips, apply blade No. 1 with its concavity over the occiput and exactly opposite to blade No. 2. When this handle is screwed home the head is crushed and flattened in the opposite diameter. This elongated diameter is now rotated until it is brought into the transverse diameter of the brim, where there is most room in cases of flat pelvis.

3. *Cranioclasm.*

In extreme degrees of contracted pelvis it may be necessary to break up and remove the calvarium piecemeal. This is a laborious and dangerous operation because of the risk of infection caused by repeated introduction of hands and instruments into the vagina. It is also difficult because in nearly every case the head is entirely above the brim, and unless the greatest care be taken it is easy to injure the maternal tissues. The operation is performed as follows: After perforating the skull, the solid blade of the cranioclast is inserted deeply into the hole with its convexity against the parietal bone. The tip of the fenestrated blade is then insinuated between the bone and the scalp at the edge of the hole made by the perforator. Having once found the line of cleavage between the two, it is easy to push the blade over the bone and

under the scalp as far as the origin of the parietal bone from the base of the skull (fig. 2141). The second blade is passed in this manner to lie opposed to the solid blade which has been previously passed, and when both are pushed home, the instrument is locked as tightly as possible. The blades have a firm grip of the parietal bone, and by a twisting action a piece of the bone is wrenched away. This is carefully drawn out, shielded by the left hand so as to protect the vagina from being scratched and torn by the sharp edges of the bone. This process is repeated until the whole of the vault of the skull is removed, and only the face and base of the skull remain. An attempt is next made to extend the head in order to produce a face presentation. This may be extremely difficult, but if it can be done the subsequent extraction will be much easier. The solid blade is forced into the mouth as far as possible and the fenestrated blade passed over the supra-orbital region, so that when the handles are screwed together the face is crushed and gripped. Having gained a firm hold, traction is made on the instrument to pull the crushed head through the brim.

EMBRYOTOMY

In some cases of obstruction it is necessary to break up the body of the fœtus. All these manœuvres are included under the term embryotomy.

Decapitation. When the child presents by the shoulder it is possible to convert it to a breech presentation during the earlier stages of labour. After the uterus has become tonic or even "irritable," with short and imperfect relaxation, version is dangerous on account of the risk of rupture of the lower segment. At this advanced stage of labour the

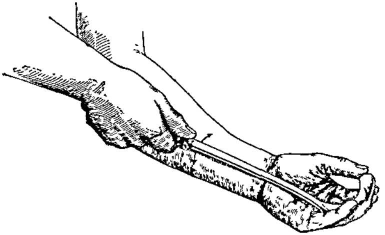

Fig. 2142.—Shows the method of introducing the decapitation hook, whereby the left hand prevents it from injuring the vagina.
(*From Eden and Holland's "Manual of Midwifery."*)

child is invariably dead, and can only be safely delivered by decapitation. Division of the neck breaks the obstructing wedge, and allows first the body to be delivered, and then the head. For all shoulder presentations when the child is dead it is advisable always to decapitate rather than to perform version if there is any risk of the lower segment having become dangerously thin by the previous action of strong fundal contractions. The prolapsed cord will readily give information as to the condition of the fœtus, and an inspection and careful palpation of the abdomen will determine, firstly, if the uterus is contracting very strongly, and, secondly, if there is a palpable ridge and groove between the upper and lower segments, commonly called the retraction ring of Bandl. Unless the uterus relaxes freely between contractions, or in the presence of Bandl's ring, version is too dangerous and must not be attempted. Even if the contractions are considerably reduced by anæsthesia, the lower segment still remains very thin and must suffer great strain during the process of version.

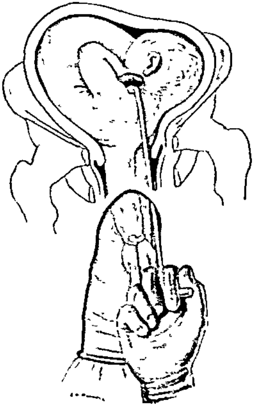

Fig. 2143.—Decapitation. Note the finger of the left hand which has guided the tip of the hook over the neck.

Operation. The patient is anæsthetised, placed in the lithotomy position, and most carefully disinfected with tincture of iodine or any other suitable disinfectant. An assistant pulls on the prolapsed hand in order to bring the neck well down over the brim of the pelvis. The left hand explores the conditions inside, and then shields the shard decapitation hook as it is passed up in front of the prolapsed arm (see fig. 2142). The shaft of the hook is passed so that it lies towards the head, and the point in the direction of the breech. Great care must be taken, as the hook reaches the level of the shoulder, not to damage the tissues behind the symphysis. The hook must be " eased " by the left hand rather than forcibly pushed by the right hand (fig. 2143).

As soon as the hook is high enough to allow the tip to clear the child's shoulder, it is turned to bring it at right angles over the neck. The left hand is then partially withdrawn and passed up on the posterior aspect of the neck in order to feel for the point of the hook. When the tip is safely covered by the fingers the hook is gently but firmly pulled down over the neck. At this stage there is danger of wounding the rectum or other soft tissues by the tip of the hook unless the fingers of the left hand are careful to act as a shield.

Before the act of cutting through the neck, the left hand ascertains that the hook fits snugly over the narrowest part of the neck, and is not

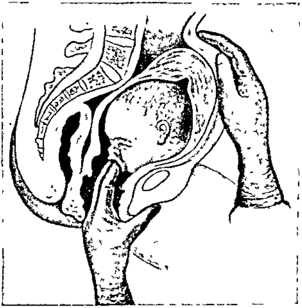

Fig 2144.—Extraction of the head after decapitation by a finger in the mouth assisted by strong fundal pressure. This is only successful if the head is small.
(From "Queen Charlotte's Text Book of Obstetrics")

lying obliquely over the neck and one shoulder. The actual decapitation is carried out by a pendulum action of the hook in the sagittal plane. The handle is carried forwards (or upwards) towards the symphysis, and then pulled strongly downwards and backwards. At the end of the down stroke it is brought back to the upper position without traction, and then again it is pulled strongly down and back. During all these movements the fingers of the left hand are held carefully on the tip to ensure that it does not injure the maternal tissues.

The hook does not cut through the upper skin of the neck easily, but after this is divided, it quickly passes through the soft tissues and even through the spine. The lower skin is apt to be pulled down by the hook before it is cut, and care must be taken at this stage that not too much traction is made with the down stroke, or the skin will be suddenly divided and the hook will thereupon be pulled hard downwards, with

the risk of striking the rectum or sacrum through the posterior vaginal wall.

When the neck has been divided, pulling on the prolapsed arm will deliver the child's body. The head remains above the brim—often a difficult problem. If the pelvis is normal it is usually a simple matter to insert the fingers into the mouth, produce a face presentation, and then draw it down assisted by strong fundal pressure (fig. 2144). The hole in the spinal canal will allow some of the cerebral matter to escape, but where the pelvis is definitely contracted it may be necessary to crush the head in the usual way, after perforating the cranium.

If the uterus is in tonic contraction, decapitation is an anxious and dangerous operation, because even the introduction of the hand and hook may rupture the extremely thin lower segment. No amount of anæsthesia or other drugs (such as amyl nitrite) can render the lower segment less thin and fragile, even though the tone of the fundus may be relaxed.

CLEIDOTOMY

Difficulty in delivery of the shoulders is common where the child is unusually large, in some cases of anencephaly, in contracted pelvis, and in the rare condition of contraction ring (hour-glass contraction of the uterus). The operation of cleidotomy consists in cutting through the clavicles with a strong pair of blunt-pointed scissors, whereby the inter-acromial diameter is considerably reduced. It is, of course, only possible when the child is dead. In cases of difficulty at the outlet due to the shoulders when, for example, the perforated head has easily been delivered, it is a simple matter to pass a pair of scissors just inside the vulva alongside the neck, and to divide each clavicle, but when the shoulders are held above the brim, this may be very difficult.

The scissors are passed in the same way as the perforator, that is, carefully shielded by being enclosed in the left hand. Each clavicle is carefully located and divided. During the actual cutting, the left hand must ensure that no maternal parts, such as a lip of the cervix, are in danger. It is usually impossible to divide the clavicles of shoulders which are held above a contraction ring, owing to the height above the vulva and the tightness of the ring.

EVISCERATION

Certain fœtal deformities of the chest and abdomen causing great enlargement may obstruct delivery, or else the pelvis may be so extremely contracted that it is impossible to deliver the trunk. Occasionally, in impacted shoulders presentations, the operation of decapita-

tion may be too dangerous until the bulk of the child's body has been reduced. Evisceration consists in cutting through the abdominal or thoracic walls with strong scissors and in evacuating the viscera by the fingers. The commonest form of this obstruction is fœtal ascites. If the abdominal wall cannot be reached, it is necessary to cut through the chest wall and then through the diaphragm to evacuate the abdominal contents. If the obstruction is due to a collection of fluid, perforation of the parietes will immediately resolve the difficulty.

CHAPTER V

Primary Repair of the Vaginal Orifice

Under this heading we have departed from the customary use of the word perineum, as it is apt to be misleading. "Repair of the perineum" lays undue stress on the injury to the *perineum*, but, in fact, the inevitable injury of the posterior vaginal wall is just as serious a lesion as that of the external skin and perineal tissues. Further, the use of the word perineum leads to the impression that, if the perineal skin is found to be intact after delivery, no injury has been sustained, but only too often an inspection of the vagina just inside the orifice will show a deep and extensive tear of the posterior vaginal wall. The tendency to this injury is probably encouraged by the practice of delivering the head very slowly in an effort to allow the maximum possible stretching of the perineal tissues. By such slow delivery it is true that the actual perineal skin is saved. but there is often a deep underlying tear, which may not be recognised. In cases of difficulty due to long, slow stretching of the perineum it is much better to make the small incision known as episiotomy whereby both the perineum and vagina, by being cleanly incised, are saved from laceration.

PRIMARY COLPO-PERINEORRHAPHY

After delivery, a careful inspection of the perineum and posterior vaginal wall is made. Blood is carefully sponged away, and under a good light the heavily bruised vaginal wall is searched for a tear. It is often not easy to recognise the limits of the tear, for the tissues are discoloured, and the tear is ragged, irregular, and often multiple. There may be one central injury, or a laceration may extend up each postero-lateral wall. In some cases the perineal and vaginal lacerations may open into each other. A more serious injury may tear the perineum as far back as the sphincter, exposing, but not actually damaging it. In the worst cases the sphincter is broken, and the mucous membrane of the anal canal is torn up its anterior wall for perhaps as much as an inch.

Before inserting any stitches, therefore, it is essential to make a close examination to find out exactly which structures need repair

(fig. 2145). These operations are usually performed under the greatest difficulties. The patient is lying in a soft bed on her left side, the light is often poor, and there is frequently no assistant. Also the field of operation is being constantly obscured by blood, and the limits of the injury of the vagina are not easy to define because of bruising. In a hospital clinic there is no difficulty, but the conditions of a private house may make a correct repair by accurate apposition almost impossible. However, as far as available assistance will allow, it is necessary to have the woman on her back at the edge of the bed, and a good light directed on to the vulva. Plenty of swabs and lotion should be at hand for cleansing the part, and, if necessary, a small plug should be pushed just into the vagina to prevent the lochial blood from constantly flowing over the site of operation. Also, have at hand a vulval self-retaining retractor, No. 2 catgut, silkworm-gut, a few artery clips, toothed dissecting forceps, a needle-holder, large curved cutting needles, and smaller ones for suturing the vagina.

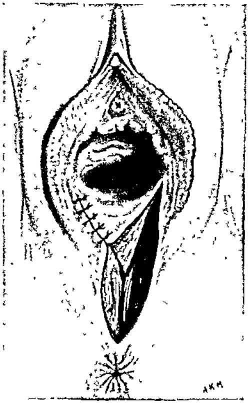

Fig 2145.—Repair of vagina and perineum.

1. *Repair of the Vagina.* The upper limit of the tear—the apex of the V—is held by dissecting forceps and the two edges of the wound are united from above downwards by interrupted sutures of catgut mounted on the smaller needles. In inserting these stitches it is a great convenience to use a needle-holder. The bite of the needle should be deep enough to include the deeper sub-vaginal tissue. After the first one or two sutures are inserted, the limits of the injury become more obvious, and when one tear has been repaired, any other tear also becomes easier to define. The whole vaginal wall, therefore, is repaired as far as the perineum. The reconstitution of the vaginal tube alters the whole appearance of the injury and renders much clearer the work which remains to be done (fig. 2146).

2. *The Perineum.* The extent of the injury varies considerably. If it is so deep as to expose the sutured vaginal wall, a row of three or

four buried stitches of catgut should be inserted to bring together the subjacent tissues (fig. 2147). After this, the skin and subcutaneous tissues are united by silkworm-gut in large needles. It is important not to tie the tissues too tightly, and to avoid leaving dead spaces (fig. 2148).

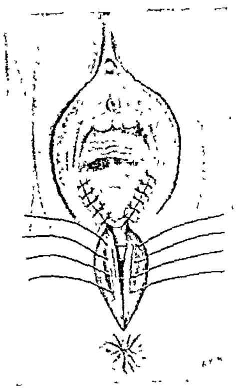

Fig. 2146.—Repair of perineum. The vagina has been sutured, and four deep catgut sutures have been inserted into the edges of the levatores ani muscles.

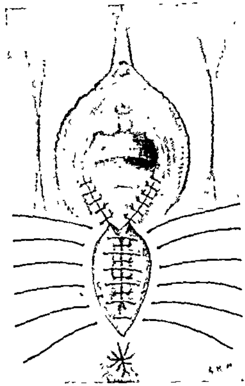

Fig. 2147.—Repair of perineum. Suture of superficial tissues over levatores ani muscles.

3. *The Anus and Rectum.* It is almost impossible to repair injury in this region without every assistance which can be obtained by the lithotomy position and a good light. In addition to the instruments previously mentioned, it is necessary to use round-bodied curved needles and thin No. 1 catgut.

The apex of the tear in the rectum is identified, and a suture of No. 1 gut threaded on a round-bodied needle is passed from the deep aspect (not the lumen) into the submucous tissue, and out exactly below the actual mucous membrane, then into the opposite edge, again immediately below the mucous membrane, and out through the submucous tissue (see fig. 2149). When this is lightly knotted the edges of the mucosa are coapted, but no catgut actually passes through the mucosa itself. If the edges of the tear are ragged, they must be carefully pared with

scissors. Tissue is brought together below the mucosa, so as to leave no dead space, or otherwise a hæmatoma will collect, which is likely to suppurate and break down the wound (see fig. 2150).

The edges of the sphincter are sought for where they will have

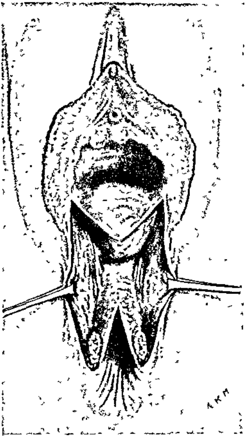

Fig 2148.—Repair of perineum Exposure of wound, with patient on her back to show extent of injury. The figure illustrates a double tear of vagina, complete rupture of perineal body and external sphincter, and tear of rectal mucous membrane.

retracted under the skin, and are sewn together, after which the overlying skin is united with silkworm-gut.

After-Treatment.

If the rectum has not been involved, no special after-care is necessary, except to keep the part clean and dry. After micturition or defæcation the area of stitches should be sponged, dried and powdered. The wound is well healed in about a fortnight, after which the patient may safely get up.

If the rectum and sphincter have been repaired, special care must be taken that, when the bowels act for the first few times, there should be no stretching of the sutured area by hard constipated scybala. To avoid scybalous formation give the patient a teaspoonful of liquid paraffin four times a day after food for the first week. This will ensure that the fæces remain soft, because the small repeated doses are effectual along the whole length of the intestine. On the fourth day the bowels must be moved by giving an aperient such as an ounce of castor oil, and an olive oil enema (4 oz.) about four hours after the castor oil has been taken, or as soon as the patient feels that the castor oil is beginning to act.

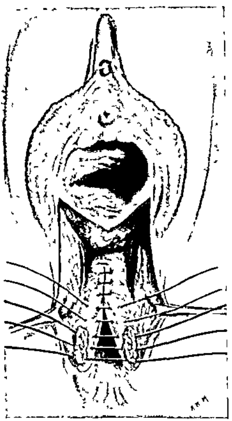

Fig 2149.—Repair of rectum. The stitches of fine catgut are being inserted up to the edges of the mucosa, and three have been tied.

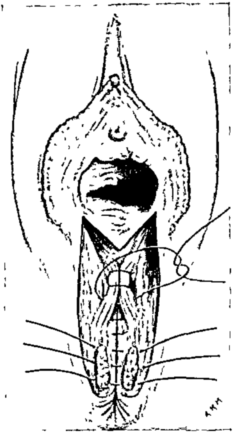

Fig 2150.—Repair of rectum. The mucosa has been united, and the overlying rectal wall is being brought together to cover and support the mucosal layer. Three stitches have been inserted into the sphincter.

During the first week the diet should be limited to milk, milk foods, custards, and potato and other vegetable *purées*.

If a perineal wound breaks down after primary repair no attempt should be made to re-suture it as there is small chance that it will heal well. It is better to cleanse it by hot dressings if necessary, and to perform perineorrhaphy about six months later.

the teachers in the clinics. It is necessary to implant the idea that obstetrics is not a branch of surgery, but an applied science of its own, which requires its own specialised consideration and technique. Certain surgical procedures may be utilised for unusual circumstances when purely obstetric methods would fail, but they should be exceptional and not routine.

As we have already mentioned, the undisputed indication is obstruction to delivery due to pelvic contraction (or disproportion between the sizes of the pelvis and the fœtal head), not only insuperable obstruction, but any degree which is likely to involve the child in danger by excessive moulding or forceps traction. Potential or partial obstructions include various conditions, such as a transverse lie of the child before labour, certain tumours, and the vagina and its outlet being narrowed by atresia, or an over-tight repair operation done for some earlier laceration.

There may be difference of opinion over borderline cases of contracted pelvis, where increasing experience will undoubtedly reduce the incidence of the operation, but the details of this most interesting problem of obstetrics we shall discuss in a later section. Real difference of opinion is possible when we come to discuss associated diseases. The sole question at issue should be whether or not the physical effort of labour is a greater stress, from every point of view, than the abdominal operation, and whether a rapid delivery, as opposed to a protracted labour, will save the mother or child a risk inherent in such labour. There is a tendency to regard normal labour as more dangerous for the mother when some complicating condition such as cardiac disease or nephritis coexists, but it is not possible to apply a rule generally. Each case must be considered on its merits. The great majority of women with cardiac disease tolerate easy labour well, but if labour is likely to be long, painful and exhausting, then the sub-normal reserve of energy will be used up, and the heart will be seriously overburdened. For such cases Cæsarean section is obviously the better treatment. The same considerations may be applied to the consideration of almost every other complication. In general it may be said that, where labour is likely to be entirely normal, the woman suffering from the complication of an associated disease will do better after normal labour than after Cæsarean section.

INDICATIONS IN PARTICULAR

1. *Contracted pelvis.* For the older obstetricians this was almost the only indication. They divided these cases into those whose

obstruction was absolute, and those in whom it was relative. For the first group there was no choice, for the second, induction of labour was an alternative method. Nowadays, we feel that if the disproportion between the head and the pelvis is such that the child runs a risk of still birth by excessive moulding or shock, or that the mother is liable to suffer from exhaustion and laceration with their sequelæ of hæmorrhage, shock and infection, Cæsarean section is the correct method of delivery.

In practice the difficulty is to decide the prognosis of labour. Obstetrics does not offer a greater field for the exercise of clinical insight than the making of this decision. Even after years of observation and experience, every obstetrician will from time to time meet with cases in which he feels doubt, and over which he may be mistaken. The study of this problem is one of the fascinations of obstetrics, and lends to it a scope of clinical interest which can tax the most mature skill and consideration. The essential is to be able to prognose the course of labour in these cases of disproportion. A superficial or inexperienced reading of physical signs before labour will so often give the impression of obstruction or great difficulty in delivery—a prognosis that may be completely falsified by the result of labour. In such cases, not only may a prognosis of obstruction be falsified, but the junior members of the clinic may well be astounded by the extraordinary ease of labour. The quickness of the second stage and the absence of caput and moulding only serve further to surprise those who had predicted difficulty. We have previously stated that it is important to be able to diagnose real disproportion. A sound judgment will save many a woman from an unnecessary Cæsarean section or induction of labour.

An opinion requiring much experience can scarcely be based upon the written directions of a text-book. But it may be of service to suggest a few details for observation. *The operation is indicated under the following conditions :*

(*a*) *If the woman has had a previous still birth due to disproportion.* Here a history of difficult labour is not sufficient. The difficulty may have been due to an unrecognised, and therefore unrotated, occipito-posterior presentation. If the previous child was abnormally large, the probability is that the present child will be even heavier.

(*b*) *When the pelvis, by internal palpation or X-ray mensuration, shows a contraction beyond the "pelvic reserve" of the normal pelvis.* It is not easy to define this in centimetres, but should the true conjugate be less than 3½ inches (9·5 cms.) it is certain that there will be a risk of

excessive moulding and still birth. But with experience, digital examination of the pelvis gives a useful idea of its capacity, and is of more value than exact mensuration. If the sacrum can be palpated all the way up to the promontory, if the lateral walls of the cavity feel nearer together than normal, if the sub-pubic angle is narrow, and if the distance between the ischial tuberosities will not admit more than three knuckles, then the pelvis is probably too small to pass a child of average weight. But, even so, other details must be considered, such as the ease of pushing the head into the brim, and its size and attitude.

If the head is strongly flexed and lying with the occiput anteriorly, it may pass the brim, whereas the same head lying posteriorly and unflexed may be unable to descend.

Real overlapping of the head above the symphysis, if the other conditions also are taken into consideration, is usually a strong indication for Cæsarean section; and even without obvious overlapping of the symphysis, if the head cannot be pressed into the brim, or, if firm pressure on the head imparts no sensation of descent, engagement, or "spring," it is very unlikely that the head will go through. But whatever may be the mechanical conditions, such as size of pelvis and head, we must not forget that the head is moulded and driven through the pelvis by uterine contractions. If these are strong and regular, labour may be completed normally, but if the "pains" are weak and inconsequent, the same head may be unable to pass through the same pelvis. It is not, of course, always possible to prognose the type of uterine contraction, yet a large experience of women and labour, and the recognition of certain female types which may give rise to what Greenhill aptly calls "*dystrophic dystocia,*" will greatly assist in deciding whether or not a borderline case may be trusted to undergo labour. In all such cases labour should be recognised as a test or trial labour, and should only be conducted in a hospital clinic where Cæsarean section can be performed if it becomes obvious that labour cannot be terminated naturally. The most striking feature of trial labour is the large proportion of cases which do terminate naturally.

There is an uncommon variety of contracted pelvis to which allusion must be made here—the transversely contracted pelvis of Van Rooy. This type is not easy to recognise unless one is prepared to find a definite contraction of the transverse diameter and the outlet. Where this condition is definite, we feel that Cæsarean section should always be undertaken.

2. *Placenta prævia.* The treatment of this condition has altered

considerably during the last twenty-five years. There is no question now that where the pregnancy has reached the 36th week, the placenta is central, and the mother is in a good condition (i.e. she is not exsanguinated and shocked) Cæsarean section can be carried out at the price of a mortality of less than 3 per cent, whereas the risk of vaginal delivery of central cases rises to 15 per cent or even more.

If the patient is shocked by loss of blood, the operation must be deferred for some hours, during which she should be treated by blood-transfusion, morphia, and warmth. The rise of blood-pressure caused by transfusion will not induce further hæmorrhage, as in all ordinary cases of arterial bleeding. A recurrence of hæmorrhage is determined only by separation of a further portion of placenta by uterine contractions.

Partial placenta prævia seldom requires Cæsarean section in the interest of the mother, but it certainly gives the child a better chance. Where the edge of the placenta only reaches the margin of the os, it is usually sufficient to rupture the membranes and bring a leg down, or to apply Willett's forceps to the scalp.

Though Cæsarean section is a great addition to the methods of treatment of central placenta prævia, it must be regarded as carrying its own risks. Even when the mother is in good condition when the operation is done, there is a definite mortality. Most of this arises: (i) as a result of operating while the patient is in a deeply shocked condition; (ii) after attempts have been made to arrest bleeding by vaginal interference; or (iii) due to post-partum hæmorrhage after the child and placenta have been removed.

3. *Accidental hæmorrhage* (*abruptio placentæ*). There is not such a wide field for treatment by Cæsarean section as in placenta prævia. The mild cases can be well treated by medical measures or, at the most, by induction of labour by rupture of the membranes, while the severe cases are too ill to withstand the shock of laparotomy. These patients are always ill, apart from the effects of loss of blood, and actual delivery is not all they require. We would say that the operation should, as a rule, only be done for accidental hæmorrhage if the patient is carrying another handicap in the shape of contracted pelvis or malpresentation, in addition to the condition which has caused bleeding.

4. *Eclampsia.* Most authorities now agree that Cæsarean section is rarely indicated for eclampsia. For adequate treatment it is necessary that the uterus should be evacuated, but it is not only *not* necessary that this should be done rapidly and at once, but it is true that so doing is liable to add an extra burden of shock, or some other adverse influence,

which may tip the scale against the patient. There are, however, exceptional cases for which rapid delivery may offer the better chance. Any additional abnormality which may render vaginal delivery difficult should influence consideration in favour of Cæsarean section. For example, there may occasionally be great œdema of the vulva, an elderly primigravida with a tightly closed cervix before pains have begun, and certain other conditions which, being present, would either delay vaginal delivery or, which is most important, require much manipulation through the vagina. There is also room for discussion over the fulminating case, or the woman who sinks into toxic coma with suppression of urine, with perhaps no fits at all. The outlook for these women is extremely bad, and little can be expected of the operation for the mother, although it is possible that rapid delivery may save the baby.

5. *All serious obstructions likely to be offered by the soft parts are adequate indications.* Such a list includes atresia, firm repair of the perineum, and a long, hard, tight cervix in an elderly primigravida. Under this heading may also be included tumours in the pouch of Douglas below the presenting part which cannot easily be pushed up, certain cases of cancer of the cervix, and, very rarely, a cervical fibroid.

6. *There is an undefined group of women who have had previous obstetric difficulties with perhaps one or more still births.* Greenhill has well described dystrophic dystocia as a form of difficult or ill-fortuned delivery which is inherent in the woman herself, and may be anticipated in every labour. Or again, a woman may be liable to hæmorrhage, either before or after labour, recurrent adherent placenta, habitual death of the child before full term, and many other conditions, which are met with from time to time, and must be considered, each on its merit. A healed vesico-vaginal fistula, after perhaps more than one operation for its closure, should always be an indication for the operation, because distension of the vagina by the head is very liable to break down the repair.

7. *Associated diseases*, including cardiac and pulmonary diseases, nephritis, and many others, form a large group about which there are many opinions, even on an individual case. The general principle which should govern consideration of every case is whether or not the stress of labour will be greater than that of laparotomy. Usually a normal straightforward labour involves less strain on the woman than Cæsarean section, but any departure from the normal, such as pronounced inertia, may be a serious danger. This is well seen in heart disease. Women who are subjects of a degree of heart disease which

has caused a temporary breakdown during pregnancy stand a normal, quick, and assisted delivery without any striking difficulty, but if such a woman should suffer from long, painful inertia she becomes quickly exhausted and her condition is dangerous.

8. *Some fœtal conditions*, including prolapse of the cord at the beginning of labour, or a malpresentation which cannot be corrected and is dangerous, may properly be treated by Cæsarean section. Habitual death of the fœtus before term may be treated in a succeeding pregnancy by operation performed at the 36th week.

9. *A previous Cæsarean section is not necessarily an indication for all further deliveries by this method.* If the original indication was a contracted pelvis, a healed fistula, or any other condition which is inherent, then obviously the operation will be necessary for every future delivery. If, however, the indication was placenta prævia or anything which is not liable to be repeated, then a second Cæsarean is not necessary simply because the uterine wall has been scarred. But if it is probable that the scar is thin from imperfect healing due to sepsis at the time of the previous operation, then it is safer to deliver all subsequent children by Cæsarean section. This applies especially to the upper segment or classic operation. If the muscle union of the scar is imperfect because of healing by granulation in the presence of infection, rupture of the scar during labour is probable, but a similar degree of "thinning" of the scar of the lower segment operation does not offer anything like the same danger. The general considerations are the position of the scar, and the existence of fever, and therefore presumably infection during the puerperium which followed the previous operation.

CÆSAREAN SECTION DURING LABOUR

Whereas the mortality of the deliberate operation done before labour, or at its very onset before rupture of the membranes or vaginal examination, is low, not more than 1 per cent or 1·5 per cent, it rises when it is performed after the membranes have ruptured, and it rises sharply after efforts have been made to deliver by the vagina. Since the widespread adoption of the lower segment method, this statement needs modification, for experience has shown that even in the presence of infection the risks are not so great as for the old classic operation.

During labour, Cæsarean section for a live baby competes with craniotomy when the child is moribund or dead, and the indication is nearly always contracted pelvis, though not uncommon difficulties are rigidity of the cervix or inertia, prolapse of the cord or certain malpresentations. The operation is therefore proposed for the sake

of the child, because only in severe cases of contraction will craniotomy be sufficiently difficult to cause risk to the mother's life.

If the labour is a so-called *trial or test labour*, every care will have been taken, firstly, to avoid vaginal contamination, and, secondly, not to delay operation until the child has been distressed. In these conditions the end-results are likely to be as good as when the operation is done before labour begins. But it is a very different matter if the woman has been examined several times, or if forceps have been applied. The danger of infection can only be justified if the condition of the child is good enough to promise a live birth. It is necessary here to point out that, even if the child is in good condition, as judged by its heart sounds, it does not follow that it will survive a Cæsarean delivery. After a long labour following rupture of the membranes or a failed attempt at forceps delivery, the condition of the child is not so good as the heart sounds would suggest. The child suffers a definite degree of shock by abdominal delivery, and if it has already been stressed by labour and forceps, the chance of survival is poor. It is not justifiable, therefore, to subject the mother to the grave risk of Cæsarean section for the sake of a child which is likely to be still-born.

It may be said now, in the light of experience of the lower segment operation, that the classic operation is quite unjustifiable after the membranes have ruptured. Whereas the mortality is about 1 per cent when the operation is done for contracted pelvis before labour, after the membranes have ruptured and forceps have been applied it rises to the region of 28 per cent.

COMPARISON OF UPPER AND LOWER SEGMENT CÆSAREAN SECTION

There is no doubt that the classic operation is easier and quicker to perform. It can be done comfortably by most operators in 20 minutes or less, and there is no risk of injury of viscera or large vessels. The writer believes that there is still a field for this method, though in many clinics it has been entirely discarded. The chief indications are: intervention before labour has begun, that is, before the lower segment has been pulled up and defined anatomically, and if sterilisation is to be carried out at the same time. The chief disadvantage of the fundal incision, namely, rupture of the scar in future pregnancy or labour, will not therefore be a consideration. It is also a safer operation for the inexpert or occasional operator, as it demands no knowledge of anatomy, and there is no danger of visceral injury.

There are, however, many counts against the upper segment Cæsarean section. The chief is the risk of subsequent rupture of the

uterine scar. Holland gives the figure of 4 per cent. K. M. Wilson (*Am. Journ. Obst. and Gyn.*, 1926 xii, 268,), in reviewing 133 pregnancies after Cæsarean section, found 3 ruptures out of 39 women who had subsequent labour, of whom one died. Twenty per cent of the cases of rupture occur between the 7th and 8½th month (Findley, *Am. Journ. Obst. & Gyn.*, 1916, lxxiv, 411). Pulmonary embolism is much commoner after the upper than after the lower segment operation. Phaneuf (*Am. Journ. Obst. and Gyn.*, xxi, 1931, 498) describes a mortality of 3·7 per cent due to embolism after the classic, and 1·2 per cent after the lower segment operation. The writer's mortality from embolism is 1 death out of 209 upper segment operations, or 0·47 per cent (total mortality of all cases 3·2 per cent, mortality of non-urgent cases 1·4 per cent).

Other risks are intestinal adhesions and obstruction, either during the convalescence or during later years (the writer's results show 0·47 per cent mortality from this cause); adhesion of the uterus to the abdominal wall with the occasional formation of a uterine fistula; peritonitis if the uterus is opened during labour in which infection has developed before operation; and any of the complications which may follow laparotomy, e.g. ileus, pneumonia, bronchitis, and sepsis of any form.

The great advantages of the lower segment operation are that the incision in the visceral peritoneum is made low down in the utero-vesical fossa, where the risk of spread of infection is at a minimum, and where intestinal adhesions are unlikely to develop; secondly, that the uterus is incised in a part of its wall which is comparatively inactive during labour, and therefore less likely to rupture, a part which heals well, and is away from the placental site. This operation has been developed as a result of the search for a safe method of delivery during the course of labour, even if it is actually infected. The high mortality of the classic operation in these conditions rendered it unjustifiable, with the result that children were lost, and the mothers were subjected to long and lacerating delivery, perhaps after destructive fœtal operations. The lower segment operation is a great step forward, as is shown by the results of all clinics which have published their results. Phaneuf (*Am. Journ. Obst. and Gyn.*, xxi, 1931, 498) reports on the end-results of 418 operations. He reports a mortality of 5·6 per cent for the intra-peritoneal operation with the longitudinal incision, and 3 per cent for the transverse incision. Of these cases (358) 154 had been done after labour began, and 41 after the membranes had ruptured. He also reports no rupture of the scar in 14 patients who had a subsequent labour, and no adhesions in 105 cases which were operated upon again at a later date.

Skeel and Jordan (*Boston Obst. Soc. Proc.*, Nov. 20, 1934) have collected 2753 cases of lower segment operations with a mortality of 2·5 per cent (compared with a total mortality of 5·2 per cent in 3468 upper segment operations). Of these patients, 56 per cent were in labour, some for many hours, and 25 per cent had had the membranes ruptured. Greenhill reports the mortality rates as follows: classic operation, 147 cases—4·76 per cent, lower segment operation, 874 cases—1·26 per cent. He states (1930) that the entire literature records only 22 cases of rupture of the lower segment scar, of which 18 operations were done during labour.

All the evidence goes to show that the lower segment is the safer route, and that by this incision the scope of Cæsarean section is extended to include treatment of patients who have been in labour for some hours, even after the membranes have been ruptured. The special scope of the operation is therefore as a means of completing trial labour where vaginal delivery proves to be impossible, and where every care is taken to avoid septic contamination.

But despite the enthusiastic accounts of the operation, chiefly from America, it is necessary to add the warning that, no matter what may be the method and technique, it is still highly dangerous to open the abdomen and the uterus in the presence of streptococcal infection. Not only is it of great danger to the life of the mother, but it puts her to the risks of sloughing abdominal wall, vesico-vaginal fistula, chest complications, and usually of a dead baby.

Trillat of Lyons (*Bull. de la Soc. d'Obst.*, 21, 697, Nov. 1932) calls attention to the dangers of the lower segment operation when the uterus is infected. He reports the following figures:

	No.	Dead.	Percentage Mortality.
Non-infected . .	43	1	2·3%
Suspect . . .	53	3	5 6%
Febrile . . .	14	4	28·5%

He also shows the malign influence of ruptured membranes as follows:

	No.	Dead.	Percentage Mortality.
Non-ruptured . .	43	1	2·3%
Up to 12 hrs . .	32	2	6·1%
12 to 24 hrs . .	11	1	9 0%
Above 24 hrs . .	12	4	33·3%

These figures are not materially different from those of the fundal operation in the main lesson they teach.

Uterine scar. Many examinations of the uterine scar have been made at subsequent Cæsarean section. The fundal wall unites with perfect muscle-to-muscle union, provided it is sutured well and there

is no infection. If, however, the uterus is infected there will be a layer of granulation tissue between the muscle surfaces which will result in the formation of fibrous scar tissue (fig. 2151). The whole thickness of the muscle will fail to unite in parts, and in some places it may fail altogether, so that the peritoneum may come to lie in contact with the

Fig. 2151.—Uterine scar. Note the fibrous tissue uniting the edges of the muscles

Fig 2152.—Uterine scar. Muscle union has failed, and the decidua and peritoneum are in contact.

decidua (fig. 2152). It is rare for such extreme failure of union to exist along the whole length of the scar, but at intervals the scar will show deep dimples or "digital fossæ" where the peritoneum and decidua are in contact.

In the case of the lower segment the union is said to be more certain. After examining 37 specimens of scars of the lower segment incision Greenhill found results as follows:

Complete muscular union	6
Small islets of connective tissue	5
Abundant areas of connective tissue	21
Extreme "thinning" of the scar	5

"Thinning" of the scar is a very common condition, but while in the upper segment it is highly dangerous, it seems to be of much less importance in the lower segment. Ordinarily the scar shows three layers: (1) A band of "sclerotic" (fibrous) tissue; (2) a band of muscle tissue dotted with islets of fibrous tissue, probably representing the catgut suture prints; and (3) a band of normal muscle.

The causes of malunion of the lower segment incision are inclusion of islets of mucosa in the muscle stitching, formation of small hæmatomata, imperfect suture and suture material, and infection. As we might expect, the scar after incision for placenta prævia gives the highest rate of ruptures. Trillat records that of 26 ruptures 8 followed lower segment operation for placenta prævia. Greenhill divides his 37 cases into four groups according to firmness of union, and classifies them as follows:

Group 1.	"Perfect union"	6 cases
Group 2.	Mild scarring, but not enough to interfere with contraction of muscle	5 cases.
Group 3.	Much fibrous tissue, occasional distinct thinning of the scar	21 cases.
Group 4.	Great thinning; in some cases scar was less than 1·2 mm. thick ($\frac{1}{10}$th of the normal thickness)	5 cases.

From this study of scars Greenhill concludes that the conditions tending to produce a bad scar are:

1. *The operation having been done after labour has been progressing* for a long time.

2. Presence of infection, as shown by fever during the convalescence. Rupture of the membranes had, however, of itself no influence. The use of interrupted catgut sutures is better than the use of a continuous stitch.

We may sum up, therefore, by saying that imperfections of the scar of the uterine incision are of much less importance in the lower than in the upper segment, as judged by the tendency to rupture. If, therefore, Cæsarean section has to be done in the presence of infection, there will be a greater chance of obtaining a functionally good scar in the lower segment, even if there are anatomical defects. When this is added to its other recommendations it must be agreed that, as a general rule, the lower segment operation is the one of choice.

TECHNIQUE

A. *Upper Segment Cæsarean Section*

1. *Preparation of the patient and theatre.* The patient is prepared as for any simple abdominal operation. There are many modifications of procedure according to individual operations. An ordinary practice is to fix the operation for a time a few days before the expected date of labour. An aperient is given two days before, and an enema on the night before. The belly wall is shaved, washed, and painted with 2 per cent tinct. iod. in alcohol during the previous evening, and it is again painted before making the incision. A catheter is passed immediately before coming to the theatre.

There is no need to describe the theatre requirements when the operation is carried out in a hospital or private clinic, beyond stating that, in addition to the operating table, a table is needed for instruments, another to hold sterile dressings and bowls of hot saline, and a third to carry the requirements of the child—eye swabs, cord ligatures, coramine or other stimulants, and a syringe.

The surgeon employs an assistant who stands opposite, a nurse to preside over the instrument table, a nurse who shall not be surgically sterile, and a nurse whose sole duty it will be to receive the child and minister to its needs. As the child delivered by Cæsarean section is often apnœic, many obstetricians like to have a bath ready for the baby, but nowadays most of us have discarded the bath and only ask that the baby should be wrapped in a warm blanket and held quietly with its head low.

2. *Anæsthesia.* In this country the administration of anæsthetics has reached such a generally high standard that we are largely independent of local anæsthesia; but on the continent of Europe and in America local anæsthesia is still widely used. The chief point is that the minimum quantity of anæsthetic should be given before the baby is released. The ideal combination is gas and oxygen with a small admixture of ether. After the child is delivered, the ether may be pressed if a greater depth is required. No pre-operative medication, such as morphia or the barbiturates, should be given, on account of the child, but a $\frac{1}{150}$ grain of atropine, half an hour before the scheduled time of operation, is useful for checking the secretion of pulmonary mucus. The combination of gas and oxygen with ether is so satisfactory that it may well displace time-wasting methods of local anæsthetic injection. Spinal anæsthesia is very often used as, by its effect on the lumbar cord and uterine muscle, uterine contraction is encouraged. It is not advisable in cases of heart disease, or in most cases of associated illness, but for the deliberate operation spinal anæsthesia has much to recommend it.

3. *Operation.* An incision of about 6 inches long is made in the middle line, or, better, just to the right, having about 2 inches of its length above the umbilicus. The object of placing the incision high up is to ensure that the abdominal scar shall not overlie the *uterine wound to which it may become adherent.* The abdominal wall is often very thin, and care must be taken not to cut through too quickly lest any adherent gut be wounded. Having opened the abdomen, wrap the edges of the wound with a large swab on each side, tucking it well under the deep surface. In this way the whole surface of the wound and skin is covered. A hand is passed to the cornu of the uterus to find out how much the uterus is rotated to the right. This is then pulled over to the left in order to ensure that the incision in the uterine wall shall be central. Unless allowance is made for the torsion to the right, the incision may lie near the left cornu, and enter the uterine cavity by an oblique cut through the muscle. The uterus therefore is central, and the abdominal cavity has already been well packed off to prevent the spill of liquor amnii and blood into the peritoneum. For the uterine incision a fresh knife is taken to avoid infection by a knife which has already cut skin. It is often thought that the uterus must be incised quickly and the child extracted as rapidly as possible. This is quite unnecessary and wrong. If incision of the uterine wall is hurried it cannot be cut cleanly, and subsequent apposition by suture must be imperfect. By a succession of strokes of

the knife the whole thickness of the muscle is divided. After each stroke the assistant rapidly and firmly swabs in the wake of the knife. From the more superficial layers, i.e. during the first two or three strokes, the bleeding is usually free, especially if the placenta is underlying. But such bleeding is of no importance, and it should not induce one to hurry. While making the incision, care should be taken to extend it to each extremity. The whole length of the wound should be incised to an equal depth. It is important not to make the deepest part in the middle, as otherwise the extraction of the child will cause tearing of both upper and lower angles, difficult suture, and imperfect union.

As the knife steadily and deliberately divides the decidua, its edges yield apart by the protrusion of the amnion through the incision. A few delicate strokes of the knife are then made at each extremity to divide the last strands of the muscle and the decidua, so that the whole length of the incision has been utilised for exposing the amnion, or, often, the placenta. If the amnion is subjacent, there is very little bleeding at this stage, and the cleanly cut muscle edges fall away for as much as 2 inches in the middle, with the amnion projecting between. If the placenta presents, it is not so easy to recognise when the muscle has been entirely divided. But though there is much more bleeding when the placenta is on the anterior wall, care should nevertheless be taken to divide the whole thickness of the muscle from end to end.

The hand is then passed through the amnion or round the edge of the placenta to find one of the feet. This is grasped, and the child is quickly extracted and held up by its foot for a few seconds while two artery clips are placed on the cord. The cord is divided immediately, and the child is handed to the nurse who is standing to receive it in a sterilised towel. Meanwhile the assistant has pulled the fundus out of the abdomen and stuffed a large swab into the abdominal wound above the fundus to prevent the escape of coils of gut. He then takes a large towel wrung out of hot saline and wraps it around the uterus, and holds it firmly; but he should not exert any hard grip, nor should he attempt to remove the placenta while the surgeon is busy with the child. Having handed the child to the nurse, the surgeon returns to the uterus and removes the placenta and membranes. If the placenta has underlaid the incision it is a simple matter to continue the separation by inserting the hand between the placenta and uterine wall and, with a gentle sawing movement, complete its detachment. The membranes are usually easily peeled off as the placenta is gently and slowly drawn away. Great care must be taken to see that the chorion is removed

from the lower segment, and especially over the os, or the lochia will be retained. The lower segment cannot be easily inspected as it is below the incision, in darkness, and concealed by blood. Finally, the finger is passed just through the internal os, partly to dilate it, and partly to ensure that if any chorion is overlying the os, it is broken. A small fragment of chorion left attached to the lower segment is not of great importance, and need not delay the operation.

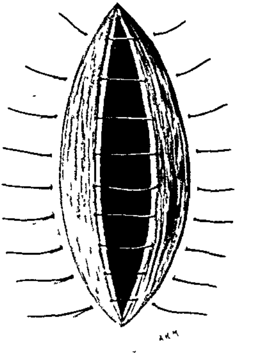

Fig 2153.—Suture of uterine wound by the first layer. Silkworm gut sutures passing through the muscle, down to, but not through the decidua.

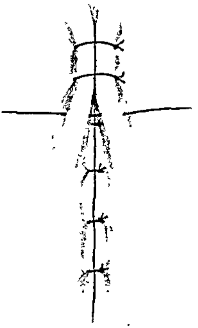

Fig 2154.—Suture of uterine wound. The insertion of the second layer of sero-muscular catgut stitches.

Suture of the Uterine Wall. There are several methods of suture. The writer has practised the same method for many years, and has no reason to alter it because of bad results. This method will therefore be described in detail.

Ease and rapidity of suture will depend to some extent on how the uterus is held by the assistant. He places each hand over a towel flat on each side of the fundus, thereby compressing the walls and retarding bleeding. The cut surfaces of the muscle then face upwards to the operator, inside the radial borders of his hands. A silkworm-gut suture mounted on a large, curved cutting needle is then entered near the lower angle of the wound at the very edge of the peritoneum fairly deeply into the muscle, down to, but not including the decidua

(fig. 2153). It is most important not to encroach on the decidua. The needle is entered on the other face of the incision just superficial to the decidua, and, with a similar bite of the muscle, brought out at the edge of the peritoneum (fig. 2154). The assistant then turns the cut surfaces of the incision inwards towards one another to bring the cut peritoneal edges together, and the silkworm-gut is tied fairly tightly by a double knot. The surgeon himself then cuts the gut close to the knot. A second needle is taken and inserted about 2 cms. (or $\frac{3}{4}$ inch) from the first, and tied. In this way the whole incision is closed by a row of interrupted silkworm-gut stitches. As the upper angle of the wound is approached, it is not possible to tie the penultimate stitch until the last has been inserted. When the first row has been inserted the whole fundus is enclosed by a hot wet towel and compressed for a few seconds, and a

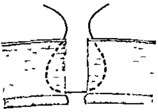

Fig. 2155.—Suture of uterine wound. A vertical diagram of insertion of the silkworm-gut suture.

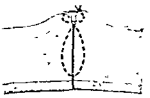

Fig. 2157.—Suture of uterine wound. Diagram of the knots tied. In the figure, the second stitch — sero-muscular — has not been tied tightly enough to bring the peritoneal surfaces into apposition.

dose of 5 units of pituitary extract is given. If it is given at an earlier stage, it may induce such strong contraction as will make the subsequent sutures " cut out."

The next and last line is a row of interrupted No. 1 catgut sutures inserted by a round-bodied, curved needle. The needle takes a Lembert bite of peritoneum and muscle on each side of the incision, at intervals between the silkworm-gut knots (fig. 2155). A further number of similar sutures is then placed over the knots (fig. 2156). By this means the silkworm-gut is entirely buried, and the thickness of the uterine wall is built up along the incision (fig. 2157).

After further pressure through a hot towel, the uterus is dropped back into the abdomen, and the utero-vesical pouch and other pockets are carefully and gently swabbed clean of blood and liquor amnii. If the uterus has been soft and flabby during the time of suture, it should be compressed in a towel from time to time, but however soft it has been, it nearly always contracts well as soon as it has been replaced.

The abdominal wall is then closed in the usual manner.

Alternative methods of suture of the uterine wall are by the use of three layers of catgut, either interrupted or continuous. The continuous suture has the objection that, as the length of the incision rapidly diminishes with involution, the catgut will become slack. This has been obvious at post-mortem examination during the puerperium. An objection to catgut is that it tends to be quickly absorbed by the autolysing muscle, and that its sterility cannot be entirely guaranteed. Thread and silk are definitely bad suture materials on account of the difficulty of ensuring sterility. Silkworm-gut can be guaranteed sterile, it is not absorbed, and it does not cause irritation of the surrounding tissues.

Holland's review of the cases of rupture of the uterine scar showed that the majority had followed the use of catgut, while there were no reported cases following silkworm-gut.

Sterilisation. For some patients sterilisation is advisable; for example, after a third Cæsarean section, or for certain associated diseases such as cardiac disease and nephritis. There are other cases also, where the indications are not so tangible, and where the patient may not care for the adventure of a repeated operation, for whom sterilisation would appear to be justifiable. The propriety of this measure will depend on many factors apart from medical details, not excluding religious and moral influences. It is important to assume a fairly rigid attitude and, while having due regard for real considerations, even if not strictly medical, we should refuse to sterilise a woman unless it seems likely that the reasons advanced to-day will be permanent.

The most certain method is bilateral salpingectomy. The important point is to excise a small piece of the interstitial portion of the tube at the cornu by a wedge-shaped incision, and to sew the edges well *together so that the tubal opening is completely buried. Unless the* opening is well covered, sterilisation is not certain. Mere ligation of the tube with silkworm-gut is useless, and so also is resection of a loop of the tube without burial of the uterine end.

After-Treatment. No special after-treatment is required beyond that for any laparotomy. The best aperient is castor oil. It should be taken after forty-eight hours, and should it be delayed in action, an enema is given. If flatulence is painful during the first two days, a turpentine enema can be given at any time.

The child should be put to the breast after twenty-four hours, and breast-feeding should be encouraged. The patient is seldom troubled with post-anæsthetic vomiting, and can therefore take solid food the next day. She should be allowed to get up on the 16th day if all is going well.

Complications. The sequelæ which are liable to follow the classic Cæsarean operation are flatulence, ileus, and even organic obstruction

due to a coil of small intestine becoming adherent to the uterine wound. Septic complications are very rare after the deliberate operation. If it has been performed upon an infected patient, sloughing of the abdominal wound, infection of the uterine wound, adhesion to the parietes, and peritonitis may all occur. In addition, these unfortunate patients are liable to septic pneumonia and its results. Acute dilatation of the stomach is not uncommon, particularly in the timid, nervous type. It shows itself after 48 hours by gastric distension, prostration, and the characteristic spurts of vomiting. Flatulence is usually overcome by enemata, either turpentine or ox-gall, combined with a simple carminative medicine. Paralytic ileus is much more serious. There is great dehydration by leakage of fluid into the gut, and prostration. If the ordinary measures for the milder cases fail, give prostigmin 5 cc. intramuscularly. Its results are remarkable. Within 6 minutes the bowel usually acts vigorously, discharging large quantities of flatus for an hour or more. In cases of peritonitis the abdomen must be opened and drained, though the outlook is almost hopeless.

B. *Lower Segment Cæsarean Section*

The patient should be in the Trendelenburg position. The incision is 6 inches long from the umbilicus to the pubes in the middle line. When the edges of the abdominal wound are retracted the lower segment and bladder are well exposed. The actual upper boundary of the lower segment is given by the limit of loose attachment of the peritoneum, which, after labour has been in progress some hours, has been pulled well up towards the umbilicus. The greater definition of the lower segment by the action of the fundal contractions renders the operation much easier than before labour has begun. The whole of the peritoneal cavity above and to the sides is well packed off by swabs. This closure of the cavity to contamination is one of the essential features of the operation. Some operators try to achieve the same object by stitching the visceral to the parietal peritoneum, but this takes longer and is probably not so efficacious.

Having exposed the field, note the line which defines the area of loose attachment of peritoneum covering the lower segment from that which is closely applied to the fundus (fig. 2158). It runs transversely across the uterus and marks the limits of the two segments. The loose peritoneum is incised transversely, about 1 inch below the line of its lower attachment, as far as the limits of the exposure. No vessels will be cut at this stage. The lower flap is easily raised, by finger dissection, carrying the bladder with it (see fig. 2159). The separation is

easy, but as the lower limits are reached, large veins may be opened at the lateral parts of the wound. These are caught and ligatured. The edge of the peritoneal flap is stitched to the lower angle of the abdominal wound to hold it out of the way. The upper flap is similarly pushed up to the limit of its loose attachment. and now *the lower segment is completely exposed.*

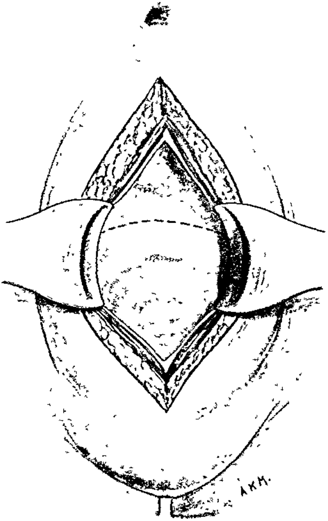

Fig 2158.—LOWER SEGMENT CÆSAREAN SECTION. THE ABDOMINAL WALL HAS BEEN OPENED (PACKS AND SWABS ARE NOT SHOWN) AND THE DOTTED LINE INDICATES THE LINE OF INCISION OF THE UTERINE PERITONEUM AT THE UPPER PART OF ITS LOOSE ATTACHMENT. IN THE FIGURE IT HAS BEEN PLACED A LITTLE TOO HIGH

Choice must now be made between a transverse and a longitudinal incision into the uterus. Most operators favour the transverse. It is difficult to find room for the longitudinal incision wholly within the anatomical limits of the lower segment before it has been pulled up by the contractions of labour. It is therefore very easy to extend the incision, or it may tear into the upper segment as the child is being withdrawn, and it is this encroachment into the upper segment that

has probably been responsible for such ruptures of the scar as have followed the lower segment operation. On the other hand, it is easier than the transverse section, and does not risk the division of the large veins at the lateral extremities of the transverse incision. The choice of incision should meet each individual case. If the woman has been in labour long enough for the lower segment to have been pulled up well, there is sufficient space for the longitudinal incision to be entirely confined to the lower segment, but if the operation is done before the onset of labour, the transverse incision is the more convenient (fig. 2160).

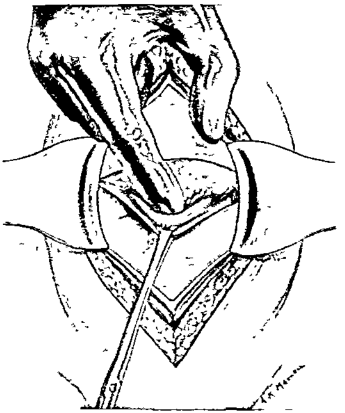

Fig. 2159.—Lower segment Cæsarean section. The peritoneum has been excised, and the lower flap is being pushed down by the finger.

Before incising the uterus, some preparation must be made for removing the blood which wells up in the deep utero-vesical space. The best method is the vacuum sucker which is found in most modern theatres, but if this is not available plentiful large absorbent packs must be at hand. A good Trendelenburg position is helpful at this stage as it allows the blood to flow away from the site of incision. One of the most important details of the technique of the lower segment method is the successful management of the effused blood and liquor amnii. This operation is done, amongst other things, in place of the classic operation, to avoid infection by contaminated liquor, and if this is allowed to spill

into the general peritoneal cavity the advantage of the sequestrated area of the lower segment is lost. Every care, therefore, must be taken in the disposal of the spilt liquor. We should not be going too far if we said that the skill and experience of the surgeon, apart from the prognosis of the operation, would be more apparent from the way he dealt with the effusion than with the actual steps of cutting and suturing.

The Incision. We will describe the transverse incision, as this is generally preferable. Some operators define the lateral limits of the

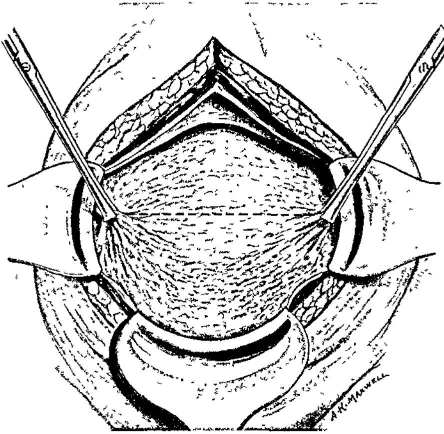

Fig. 2160—Lower segment Cæsarean section The peritoneum has been pushed up and down, exposing the muscle The dotted line shows the usual transverse incision through the muscle although occasionally a curved incision, with convexity downwards, may be used.

incision by two catgut stitches, passed deeply into the muscle, with their ends left long. They may assist in hæmostasis, and also in preventing the wound from tearing into the lateral area of the uterine wall. Or, instead of sutures, tissue forceps may be used.

Having, therefore, made every arrangement for the absorption of "spill," and defined the limits of the incision, make a transverse cut along its whole length, repeating the stroke carefully until the amnion is reached. Usually the amnion is divided as the last stroke is made through the muscle, for the wall is much thinner than that of the upper

segment. Bleeding easily obscures the wound and makes it impossible to see clearly how deeply the muscle is incised until the child's head comes into view. Another method (described by De Lee) is to make a small hole into the uterus at one end of the incision and then pass a pair of intestinal clamps, one on each side of the intended track of the cut, along its whole length. The clamps grip the muscle walls and prevent bleeding. The rest of the incision is completed by passing one blade

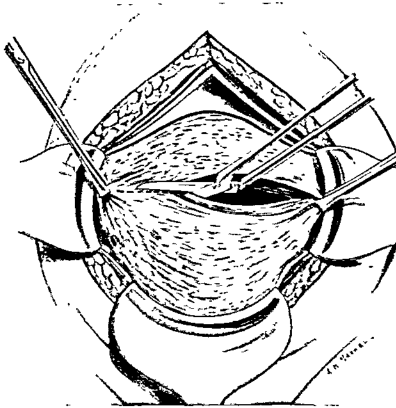

Fig. 2161.—Lower segment Cæsarean section. The incision into the uterine cavity is being made by scissors instead of by successive strokes of the knife.

of a pair of scissors through the preliminary opening, and cutting along the whole length (fig. 2161). Obvious large sinuses are then grasped by tissue forceps, and the clamps are removed.

Extraction of the Child. The occiput or parietal bone usually presents. The simplest method is to lever the head out of the incision by passing one blade of the obstetric forceps round and underneath (fig. 2162). The head is thus easily raised out of the wound, and the whole body slowly removed, first one shoulder and arm and then the other. As the head is the first part to be delivered, there is no need for subsequent hurry. Some operators apply both blades to the head and deliver the head by the ordinary method of forceps extraction. If

this is done, care must be taken to see that the head is rotated to bring *the occiput to the front.* This can be effected by traction on the scalp with a pair of tissue or Willett forceps. If the face presents it can be extracted by hooking a finger in the mouth combined with a little pressure on the sides of the lower segment. If the child's body is removed slowly after the head, time can be taken in sponging the eyes and clearing the mouth of mucus. Also the uterus has time to contract down.

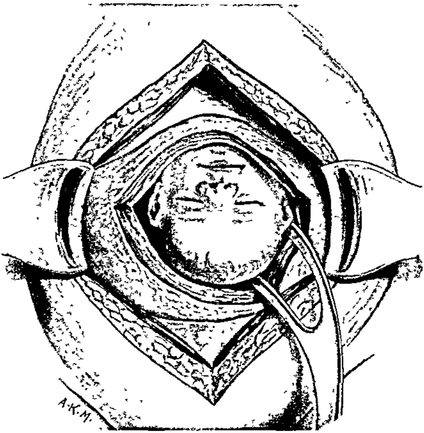

Fig. 2162.—Lower segment Cæsarean section. The head is being levered out of the lower segment by a blade of the forceps.

The Placenta. Immediately the head has been delivered the nurse injects a dose of 5 units of pituitary extract. If the edges of the wound are bleeding freely from any obvious sinuses, toothed forceps such as small vulsella are applied. Do not use a crushing clip like the ordinary artery forceps, or the muscle at the edge of the incision will be damaged. After a few moments the contracting fundus will have begun to separate the placenta and push it down into the wound. This may be encouraged by a little pressure through the abdominal wall, but it is inadvisable to compress the fundus directly as this means soiling the abdominal cavity which we have taken so much care to avoid doing. Nor is it good to pass the hand into the uterine cavity and remove it manually, although if

the separation is sluggish this may be necessary. It is better than removing the "walling-off" packing and passing the hand up into the abdomen to grasp the fundus.

Suture of the Wound. Use interrupted No. 3 catgut. The muscle wall of the lower segment is covered with a thin layer of fascia, and on its deep surface there is the decidua. Pass the first row of sutures through the thickness of the muscle only, avoiding both the fascia and decidua, and place them about ½ an inch apart (fig. 2163). A

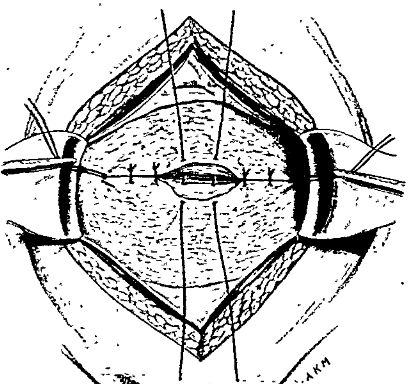

Fig. 2163.—Lower segment Cæsarean section. Insertion of first row of catgut sutures. The figure shows them passing superficial to the subjacent decidua.

few extra ones may be inserted afterwards to stop any bleeding. It is important to avoid the formation of a hæmatoma. It is well now to put in a second row of muscle stitches over the first, to cover the first row, using a fine No. 1 catgut (fig. 2164). The fascial covering is next united by interrupted thin catgut sutures, and finally the peritoneum is approximated by a continuous suture of fine catgut (fig. 2165). After all the stitching is complete, mop away gently every drop of blood, vernix and liquor amnii, carefully remove the swabs which packed off the abdominal cavity, change the gloves of both surgeon and assistant, and sew up the abdominal wall with a fresh set of instruments.

C. *Porro's Operation*

Porro devised his operation in 1877 to avoid the mortality due, in those days, to hæmorrhage and infection. It consists in removing the child through the fundal incision, leaving the placenta *in situ*, removing the uterus by the supra-vaginal amputation, and stitching the stump outside the peritoneum to the lower angle of the wound. The essential step is the last. To avoid the risk of contamination of the peritoneum. Porro felt that the stump should be extra-peritonealised.

It is still sometimes necessary to remove the uterus (Cæsarean hysterectomy), e.g. for fibroids, very occasionally for abruptio placentæ (accidental hæmorrhage) where the uterine wall is in a pathological condition and unable to contract, and also for certain rare cases of dangerous infection. But it is seldom if ever necessary now to treat the stump as advised by Porro, and performance of the operation as described by him is exceedingly rare.

D. *Extra-peritoneal Cæsarean Section*

Several methods have been devised to approach the lower segment outside the peritoneal cavity, in order to avoid the risk of peritonitis in cases of labour which are frankly septic. The best is Latzko's operation. This is much more difficult than the ordinary operation and should not be done as a routine measure, but if it is ever necessary to operate after many hours of labour, during which attempts have been made to deliver, Latzko's operation is the method of choice.

Published results by Küstner and Bumm (Berlin) show four maternal deaths in a series of 226 operations. and, in addition, Küstner injured the bladder in 7 per cent of his patients, and also had trouble from ureteral fistulæ, hæmorrhage into the broad ligament, and thrombosis. A recent paper by Fleischer and Küstner (*Surg., Gyn. and Obst.*, LXI, Nov., 1935) recommends Latzko's operation for definitely infected cases, and quotes his series of 19 in which there were no deaths, and only four patients who had serious post-partum complications. They remark upon the small amount of hæmorrhage and shock.

Technique. (Quoted by De Lee—*Principles and Practice of Obstetrics.*) Briefly the technique is as follows: The patient is in the Trendelenburg position, and 150 cc. of saline have been injected into the bladder. The catheter is left *in situ* and clamped. The incision is sub-umbilical, and about an inch to the left of the middle line. The knife is carefully carried down to the peritoneum, which must on no account be opened or pricked. In the lower part of the wound the peritoneal fold is sought for and pushed up from the lower segment and bladder. The bladder is recognised by reason of its contained saline,

and then emptied by unclamping the catheter, which is still left in position. The bladder is then carefully peeled off the uterus by pushing it downwards and to the right, while the utero-vesical peritoneal fold is also pushed to its upper limit, off the lower segment. If the woman has been in labour for some time, the lower segment has been pulled up, and a fair area of it is available. *Some care and time is necessary for this* dissection, and all vessels must be tied lest a hæmatoma should form in the space of Retzius. Loose blood is the chief cause of abscess formation later. When the maximum length of the lower segment has been exposed, the lateral areas are thickly padded by swabs to absorb blood (there will be little liquor amnii since the membranes will have been ruptured for some hours in a patient for whom this operation has been selected). A longitudinal incision in the lower segment is made by first making a small hole with a knife at its upper extremity and then completing it with blunt-pointed scissors. The wall will be very thin at this stage of labour. The table is then returned to the horizontal position and the head extracted as described in the previous section. Take care to deliver the child very slowly. When the head has been extracted, take time in sponging the eyes and mouth. The child will certainly be shocked and in poor condition before the operation is begun, therefore do not add to the shock by rapid delivery. Deliver each shoulder slowly and tenderly, and then slowly withdraw the body, quickly clamp the cord, and immediately wrap the child in a warmed blanket and instruct the nurse to place it on an inclined surface with the head down. *Apart from an injection of coramine and a gentle jet* of oxygen and carbon dioxide (7 per cent) playing over the mouth and nose, no other treatment should be administered. On no account should the child be made a victim of artificial respiration.

The wound in the uterus should be sewn up as previously described, and the bladder and peritoneal pouch brought back into position. Any bleeding point is ligatured, the area is carefully mopped dry, the swabs are removed, and a small rubber drain is inserted for 24 hours. The abdomen is closed in the usual way.

SUMMARY OF INDICATIONS FOR THE VARIOUS METHODS OF CÆSAREAN SECTION

The classic operation should only be undertaken *before labour has* begun, for deliberate cases, for certain cases of placenta prævia, where it may be necessary to operate as quickly as possible, in short, for all emergencies where the patient must spend the minimum time on the table. It should also be the operation *of choice for the inexpert and* occasional operator, faced with an emergency, and for all cases where

old adhesions or obstructing fibroids would render the approach to the lower segment difficult.

The lower segment operation has become elective in nearly all clinics abroad and in Scotland, but it has not yet become widely adopted in London. It is specially suitable after labour has begun, i.e. for all trial labours, and in all cases of suspected infection. If, however, for any special reason abdominal delivery must be carried out where infection is certain, perhaps the safest method is the extra-peritoneal method of Latzko. It is, however, difficult, long, and has its own special risks, and it can only be justified by some special importance attached to a child, which, despite efforts at delivery, is still in good condition. Truly, a very rare combination of circumstances!

As a competitor with Latzko's operation, that of Porro would be the winner. It is easier, quicker, and more certain to eradicate the source of infection. Its opponents claim that the peritoneal cavity is opened, and therefore the woman is put to a greater risk of fatal infection. But is it yet certain that the pelvic cellular tissue is more resistant to a rapidly permeating infection than the peritoneum? The writer's experience is that the cellular tissue of the space of Retzius and the base of the broad ligament is more vulnerable than the peritoneum, and of the two operations, Latzko's and Porro's, he feels that the latter is the safer.

The variations of the Cæsarean technique all have for their object the extension of the abdominal delivery to save a child which is still alive, without risking the mother's life by sepsis. Before, or early in, uncontaminated labour there is no problem. But after the membranes have been ruptured many hours, if the child is still alive, there is a problem indeed! We feel that the child, in these circumstances, is never so well as it seems by auscultation, and that, as a rule, Cæsarean delivery at great risk to the mother will yield a child, which, if not born dead, will, after a few gasps, sink into death. It has further to be remembered that success by these desperate operations can only be achieved by expert professional operators who are not often available. *The general practitioner operator, who is usually the one to be faced with these emergencies, cannot be expected to succeed, and he should not attempt them.* What is gained by the delivery of a dead baby from a mother who, even if she survives, will have a stormy, infected convalescence, with the great risk of rupture of the scar in a future pregnancy because of imperfect and infected uterine suture? For these unfortunate women craniotomy is the safer procedure. A little time more and the child will be dead. No prejudices are therefore offended, and the mother will live to have more children.

CARDIO-VASCULAR SURGERY

by

A. J. COKKINIS

CARDIO-VASCULAR SURGERY

Introduction and Historical Review

Cardio-vascular surgery embraces two very different entities. One is the *surgery of the blood-vessels,* which dates its birth from the very dawn of history, deals with such common conditions as arterial and venous wounds, varicose veins, phlebitis, arterial occlusions, etc., and mostly concerns itself with easily accessible and " safe " regions. The other is the *surgery of the heart,* the infant of the surgical art, no older than the present generation, and concerned with the most vital and least accessible of human organs, but already a field of great achievement, and of even greater promise.

Probably the earliest of all surgical procedures was the arrest of bleeding from a wounded vessel by pressure. The ancient Hindus, the great surgeons of antiquity, were familiar with every method of controlling hæmorrhage except the ligature, while blood-letting undoubtedly had its birth in prehistoric times. The first golden age of vascular surgery, however, came in the second century A.D., almost entirely from the work of Greek surgeons. In this century *Heliodorus* first described ligature and torsion of blood-vessels, and *Antyllus* founded the operative treatment of aneurysms with the extremely rational procedure which still bears his name (see page 4062). Also in the second century *Galen* proved that the arteries contain blood, and that a ligated artery pulsates proximal to the ligature, but not distal to it. During the Byzantine period an important contribution was made by *Aetius* in the sixth century, to whom is due the first description of proximal ligature for aneurysm.

After the hiatus of the Dark Ages, vascular surgery shared in the awakening of medical knowledge at the Renaissance. Late in the thirteenth and early in the fourteenth centuries important additions were made by three mediæval surgeons: *Saliceto,* who showed how to diagnose an arterial wound by the spurting of blood, and *Lanfranc* and *Henri de Mondeville,* who arrested hæmorrhage by digital pressure, ligature, and styptics, and were familiar with torsion and acupressure. For some centuries after this it was fashionable to treat wounds and arrest hæmorrhage with boiling oil or cauterisation. Great credit is

CHAPTER I

Surgery of the Heart

SURGICAL ANATOMY AND PHYSIOLOGY OF THE HEART AND PERICARDIUM

Until quite recently the heart was the only important organ the anatomy and physiology of which was not of material concern to the surgeon. This is no longer the case. The heart is now coming into the province of surgery to an extent undreamed of twenty years ago, and the surgeon who aspires to operate upon it must acquire an accurate knowledge of its anatomy and physiology. The importance of its exact position and surface relations, and of the bearing these have on the problems of surgical approach, is obvious. No less essential is a knowledge of its pericardial and other relations, of its blood supply, and of its intrinsic and extrinsic neuro-muscular mechanisms.

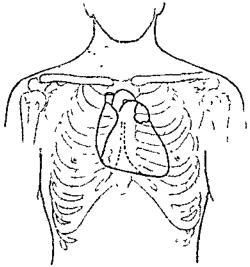
POSITION AND RELATIONS

The heart, enclosed in the pericardium, lies obliquely in the widest part of the middle mediastinum, the space between the two pleural sacs, which is bounded below by the diaphragm and above by an imaginary plane passing from the lower border of the fourth dorsal vertebra to the lower border of the manubrium sterni. *Posteriorly*, the pericardium is separated from the middle four dorsal vertebræ by the contents of the posterior mediastinum, the œsophagus being an immediate contact relation and intervening between it and the descending aorta and thoracic duct. *Laterally*, the pericardium is in close contact with the mediastinal pleura on both sides, the phrenic nerves running down between them a little in front of the pulmonary roots.

varies with the size and build of the patient, and with the presence or absence of bulging of the pericardium or heart; under average conditions the apex of the triangle is at the level of the fourth costo-sternal junction, its base is at the sterno-xiphoid junction, its right margin runs down almost vertically a little to the right of the mid-line, while its left margin slopes down and to the left to meet the base on the sixth left costal cartilage, at a variable distance from the sternum (usually one to two inches). The triangle is thus almost entirely to the left of the mid-line.

The actual topography or *surface marking* of the heart is made clear in fig. 2166, without the need of detailed description. About two-thirds of the organ lie in the left half of the thorax, and one-third in the right half. The surface relations of the heart chambers are roughly as follows: behind the sternal ends of the right

Fig 2166.—Surface relations of heart and pericardium.



costal cartilages is the right auricle, with a little of the right ventricle; behind the sternum is the right ventricle, with the roots of the aorta and pulmonary artery; and behind the left cartilages are the left ventricle and auricle.

Exterior of Heart (figs. 2167 and 2168).

The heart is conical and lies free in the pericardial sac except at its base, where it is fixed by the great vessels which enter and leave it. The *base*, or posterior surface (fig. 2167), looks backwards, upwards, and to the right, and is made by the quadrilateral left auricle (receiving the right and left pulmonary veins), assisted by the posterior surface of the right auricle (receiving the superior and inferior venæ cavæ). The auricles are prolonged forwards into auricular appendices, and between them form a crescent which embraces the roots of the aorta and pulmonary artery; an interauricular groove separates the bodies of the two auricles posteriorly. The *apex* of the heart is directed downwards, forwards, and to the left, and is made entirely by the left ventricle.

The *anterior surface* (fig. 2168) is convex and looks upwards as well as forwards. The greater part of it is made by the right ventricle, but to the right of this can be seen the anterior part of the right auricle, with its appendix, the right auriculo-ventricular groove intervening. To the left of the right ventricle is a narrow area

CHAPTER I

Surgery of the Heart

SURGICAL ANATOMY AND PHYSIOLOGY OF THE HEART AND PERICARDIUM

Until quite recently the heart was the only important organ the anatomy and physiology of which was not of material concern to the surgeon. This is no longer the case. The heart is now coming into the province of surgery to an extent undreamed of twenty years ago, and the surgeon who aspires to operate upon it must acquire an accurate knowledge of its anatomy and physiology. The importance of its exact position and surface relations, and of the bearing these have on the problems of surgical approach, is obvious. No less essential is a knowledge of its pericardial and other relations, of its blood supply, and of its intrinsic and extrinsic neuro-muscular mechanisms.

POSITION AND RELATIONS

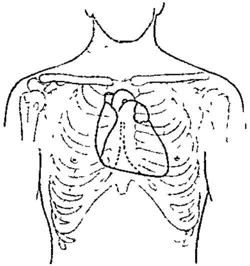
The heart, enclosed in the pericardium, lies obliquely in the widest part of the middle mediastinum, the space between the two pleural sacs, which is bounded below by the diaphragm and above by an imaginary plane passing from the lower border of the fourth dorsal vertebra to the lower border of the manubrium sterni. *Posteriorly*, the pericardium *is separated from the middle four dorsal vertebræ* by the contents of the posterior mediastinum, the œsophagus being an immediate contact relation and intervening between it and the descending aorta and thoracic duct. *Laterally*, the pericardium is in close contact with the mediastinal pleura on both sides, the phrenic nerves running down between them a little in front of the pulmonary roots.

Anteriorly, the heart and pericardium are very largely overlapped by the thin front margins of the lungs and pleuræ, which separate them from the lower three-quarters of the body of the sternum, and from the sternal ends of the costal cartilages attached to it (3, 4, 5 and 6). There is, however, an extremely important *triangular area*, opposite the cardiac notch on the front margin of the left lung, where the pericardium is uncovered by the pleura, and where it is immediately related to the left half of the sternum, below the fourth left costal cartilage, and also to the sternal ends of the fifth and sixth left cartilages (fig. 2166). This triangular area constitutes the so-called "*triangle of safety*," and indicates the best approach for exposure and needling or drainage of the pericardial sac. Its size

varies with the size and build of the patient, and with the presence or absence of bulging of the pericardium or heart; under average conditions the apex of *the triangle is at the level of the fourth costo-sternal junction, its base is at the* sterno-xiphoid junction, its right margin runs down almost vertically a little to the right of the mid-line, while its left margin slopes down and to the left to meet the base on the sixth left costal cartilage, at a variable distance from the sternum (usually one to two inches). The triangle is thus almost entirely to the left of the mid-line.

The actual topography or *surface marking* of the heart is made clear in fig. 2166, without the need of detailed description. About two-thirds of the organ lie in the left half of the thorax, and one-third in the right half. The surface relations of the heart chambers are roughly as follows: behind the sternal ends of the right

Fig. 2166.—Surface relations of heart and pericardium



costal cartilages is the right auricle, with a little of the right ventricle; behind the sternum is the right ventricle, with the roots of the aorta and pulmonary artery; and behind the left cartilages are the left ventricle and auricle.

Exterior of Heart (figs. 2167 and 2168).

The heart is conical and lies free in the pericardial sac except at its base, where it is fixed by the great vessels which enter and leave it. The *base*, or posterior surface (fig. 2167), looks backwards, upwards, and to the right, and is made by the quadrilateral left auricle (receiving the right and left pulmonary veins), assisted by the posterior surface of the right auricle (receiving the superior and inferior venæ cavæ). The auricles are prolonged forwards into auricular appendices, and between them form a crescent which embraces the roots of the aorta and pulmonary artery; an interauricular groove separates the bodies of the two auricles posteriorly. The *apex* of the heart is directed downwards, forwards, and to the left, and is made entirely by the left ventricle.

The *anterior surface* (fig. 2168) is convex and looks upwards as well as forwards. The greater part of it is made by the right ventricle, but to the right of this can be seen the anterior part of the right auricle, with its appendix, the right auriculo-ventricular groove intervening. To the left of the right ventricle is a narrow area

of left ventricle, forming the thick and rounded left border of the heart, with the anterior interventricular groove intervening. The upper end of this groove is hidden by the left auricular appendix, which projects round from behind. Between the two auricular appendices can be seen the roots of the pulmonary artery and aorta, the former lying to the right and in front of the latter at their commencement.

The *inferior surface* (fig. 2167) is flat and lies on the central tendon of the diaphragm. It is formed mostly by the left ventricle and completed by the right ventricle, with the inferior (or posterior) interventricular groove separating them.

Internal Mammary Artery (fig. 2169).

The exact position of this vessel is of importance, both in the operative approach to the heart and pericardium, and in the diagnosis of precordial wounds.

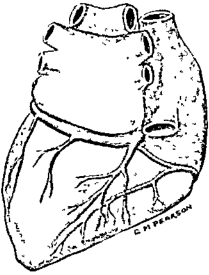


Fig 2167 —POSTERIOR AND INFERIOR ASPECTS OF HEART

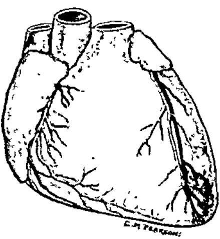

Fig. 2168.—ANTERIOR ASPECT OF HEART.

Arising from the first part of the subclavian, it passes down behind the inner end of the clavicle, and behind the inner portion of all the costal cartilages down to the sixth Accompanied by its venæ comites it lies a quarter to three-quarters of an inch from the edge of the sternum. In front of it are the costal cartilages and intercostal muscles, with the anterior ends of the upper six intercostal nerves. Behind it is the pleura and triangularis sterni muscle; below the level of the fourth costal cartilage the left artery has the pericardium as a posterior relation (in the region of the " triangle of safety "). Reaching the sixth intercostal space, the artery divides into its superior epigastric and musculo-phrenic branches.

The Coronary Vessels (figs. 2170 and 2171).

A knowledge of the anatomy and physiology of the coronary circulation is essential in practically every form of surgical intervention upon the heart. Thus, a main vessel may be included in the suture of a heart wound, with disastrous results, or such a vessel may be pricked in needling for pericarditis, with the production of an intrapericardial hæmorrhage and a fatal acute compression

(tamponade) of the heart. Similarly, a coronary vessel may be torn during the operation of freeing the heart in adherent pericarditis. The physiology of the coronary circulation is particularly important in the very recent surgical procedures

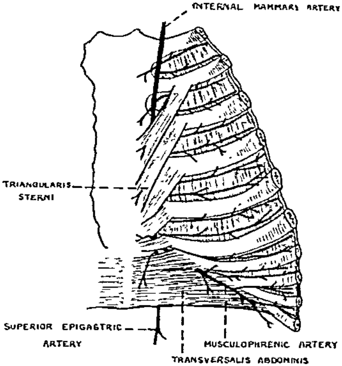

Fig. 2169.—INTERNAL MAMMARY ARTERY.

directed to the relief of angina pectoris, organic coronary disease, and other vascular lesions of the heart.

The *coronary arteries* (fig. 2170) are two in number, right and left, and arise from the sinuses of Valsalva at the very commencement of the ascending aorta.

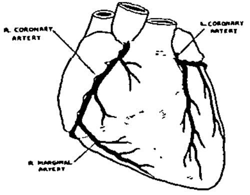

Fig. 2170.—THE CORONARY ARTERIES.

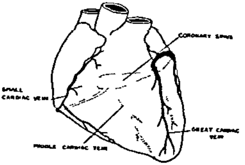

Fig. 2171.—THE CARDIAC VEINS.

They lie on the surface of the heart, embedded in a variable amount of fat. The *right coronary* runs forward between the right auricular appendix and the root of the pulmonary artery, and then down in the right auriculo-ventricular groove, on the anterior surface of the heart. Reaching the inferior surface, the artery gives off a *right marginal branch*, which runs along the lower margin of the heart, towards the apex, and then divides into its two terminal branches: of these, the

facilitates movement, at the same time deprives the greater part of the heart from contact with its environment, and thus from acquiring a collateral source of vascular supply. Normally, the only continuity is by means of the scanty fat, nerves and lymphatics on the walls of the great vessels which enter or leave the heart base. That even this very poor scaffold for an extra-cardiac anastomosis is capable of adequate development is shown by the occasional survival of cases of occlusion of both coronary arteries, but the closure has to be extremely slow for this to happen. In the vast majority death occurs long before a functioning anastomosis can develop. The provision of an abundant collateral vascular bed by surgical operation is one of the most brilliant achievements of surgical research, and will be dealt with in a subsequent part of this section.

The *internal anastomoses* of the coronary circulation have been thoroughly investigated by Leriche and Fontaine, and prove to be functionally efficient up to a point. Ligature of a coronary trunk always causes death from fibrillation, but ligature of a main branch below the first collateral is followed by recovery with a small infarct or a patch of fibrosis in the ventricular wall. These experimental results have been confirmed by radiological studies of opaque injections into the coronary arteries, and by electrocardiographic studies, and the entire research shows conclusively that the internal anastomoses can revascularise an ischæmic territory, provided the occlusion does not involve one of the main coronary vessels.

INNERVATION OF THE HEART

Intrinsic Mechanism. The nerves entering the heart are branches of the right and left *coronary plexuses*, which accompany the coronary arteries, and supply the corresponding heart chambers. Small ganglia are present in the coronary plexuses, in the nerves which supply the auricular walls, and in those which supply the ventricular walls in the immediate vicinity of the auriculo-ventricular grooves.

The coronary plexuses are derived from the *cardiac plexus*, which has superficial and deep portions (fig. 2172). The *superficial cardiac plexus* lies below the concavity of the aortic arch, and receives the superior cardiac branch from the *left* superior cervical sympathetic ganglion, and the inferior cardiac branch of the *left* vagus ; this cardiac plexus is prolonged into the *right* coronary plexus. The *deep cardiac plexus* is found on the trachea behind the aortic arch, and receives the middle and lower cardiac branches of the *left* sympathetic, and the superior cardiac branches of the *left* vagus, as well as all the cardiac branches of the *right* sympathetic and vagus. The deep plexus is continued into the *left* coronary plexus, and assists the superficial plexus in making the *right* coronary plexus.

The above description must be taken as an average arrangement, since there are considerable variations.

The *propagation* and *conduction* of the *heart's contraction* is now known to be the function of a special tract of heart muscle (fig. 2173) which starts at the *sino-auricular node*, a small thickening in the wall of the right auricle just below the entrance of the superior vena cava. This node is regarded as the pace-maker in which the heart's beat originates. From it rather indefinite muscular fibres can be traced to a well-defined *auriculo-ventricular node* (of Tawara), situated in the wall of the right auricle a little below the mouth of the coronary sinus. The node of Tawara forms the starting point of the *auriculo-ventricular bundle* of His,

transverse branch runs to the left in the left auriculo-ventricular groove to anastomose with the transverse branch of the left coronary, while the *descending branch* passes forward in the inferior interventricular groove to the apex of the heart, where it anastomoses with the descending branch of the left coronary.

The *left coronary artery* passes to the left behind the root of the pulmonary artery and appears on the surface by coming forwards between this artery and the left auricular appendix. Here it immediately divides into a *transverse branch* which runs back in the left auriculo-ventricular groove to anastomose with the same branch of the right coronary, and a *descending branch* which passes down in the anterior interventricular groove to the apex, where it anastomoses with the descending branch of the right coronary. From the transverse branch is given off the *left marginal artery*, which runs along the rounded left border of the heart.

The *cardiac veins*, in the main, accompany the coronary arteries, but their arrangement is somewhat different (fig. 2171). Associated with the left coronary artery is the left or *great cardiac vein*; this starts at the apex of the heart, and runs up the anterior interventricular groove, to open into the left extremity of the *coronary sinus*. This wide sinus is about an inch long, lies in the posterior part of the left auriculo-ventricular groove, and opens into the right auricle. In addition to the great cardiac vein, the coronary sinus receives the *middle cardiac vein*, which runs back in the inferior interventricular sulcus, accompanying the descending branch of the right coronary artery, and the right, or *small cardiac vein*, which lies in the right auriculo-ventricular groove with the trunk of the right coronary artery. The marginal arteries are also accompanied by corresponding veins.

PHYSIOLOGY OF THE CORONARY CIRCULATION

The coronary circulation is adapted to the heart's needs by its *vasomotor control*. Unfortunately, there appears to be radical disagreement as to the nature of this control. Until recently Anrep's conclusion that the coronary vasomotor nerves functioned in an opposite manner to that of other vascular nerves was generally accepted. Working on dogs in 1926, he showed that stimulation of the vagus produced vasoconstriction, and that sympathetic stimulation caused vasodilatation of the coronary arteries. On the other hand, Leriche and Fontaine in 1932, also working on dogs, came to the opposite conclusion, viz. that the vasomotor control of the coronary arteries is precisely similar to that of cutaneous and splanchnic vessels; in other words, that the sympathetic is the coronary vasoconstrictor. These seemingly irreconcilable conclusions have been bridged to some extent by the more recent perfusion experiments on the revived human heart reported by Kountz, Pearson and Koenig in 1934; they show that under normal conditions stimulation of the vagus increases the coronary flow. while sympathetic stimulation reduces it, but that in the presence of dissociation of auricular and ventricular contraction the reverse occurs. Although we may conclude that the sympathetic is probably vasodilator to the coronary arteries, these experiments show that *the heart's rate and muscular activity play a more important part in the regulation of the coronary blood-flow* than does the size of the coronary vessels.

Another important matter recently investigated is the *external anastomosis* of the coronary arteries, and the possibility of providing a *collateral blood supply* to the heart in the event of coronary occlusion. The serous pericardial sac, which

facilitates movement, at the same time deprives the greater part of the heart *from contact with its environment, and thus from acquiring a collateral* source of vascular supply. Normally, the only continuity is by means of the scanty fat, nerves and lymphatics on the walls of the great vessels which enter or leave the heart base. That even this very poor scaffold for an extra-cardiac anastomosis is capable of adequate development is shown *by the occasional survival of cases* of occlusion of both coronary arteries, but the closure has to be extremely slow for this to happen. In the vast majority death occurs long before a functioning anastomosis can develop. The provision of an abundant collateral vascular bed by surgical operation is one of the most brilliant achievements of surgical research, and will be dealt with in a subsequent part of this section.

The *internal anastomoses* of the coronary circulation have been thoroughly investigated by Leriche and Fontaine, and prove to be functionally efficient up to a point. Ligature of a coronary trunk always causes death from fibrillation, but ligature of a main branch below the first collateral is followed by recovery with a small infarct or a patch of fibrosis in the ventricular wall. These experimental results have been confirmed by radiological studies of opaque injections into the coronary arteries, and by electrocardiographic studies, and the entire research shows conclusively that the internal anastomoses can revascularise an ischæmic territory, provided the occlusion does not involve one of the main coronary vessels.

INNERVATION OF THE HEART

Intrinsic Mechanism. The nerves entering the heart are branches of the right and left *coronary plexuses*, which accompany the coronary arteries, and supply the corresponding heart chambers. Small ganglia are present in the coronary plexuses, in the nerves which supply the auricular walls, and in those which supply the ventricular walls in the immediate vicinity of the auriculo-ventricular grooves.

The coronary plexuses are derived from the *cardiac plexus*, which has superficial and deep portions (fig. 2172). The *superficial cardiac plexus* lies below the concavity of the aortic arch, and receives the superior cardiac branch from the *left* superior cervical sympathetic ganglion, and the inferior cardiac branch of the *left* vagus; this cardiac plexus is prolonged into the *right* coronary plexus. The *deep cardiac plexus* is found on the trachea behind the aortic arch, and receives the middle and lower cardiac branches of the *left* sympathetic, and the superior cardiac branches of the *left* vagus, as well as all the cardiac branches of the *right* sympathetic and vagus. The deep plexus is continued into the *left* coronary plexus, and assists the superficial plexus in making the *right* coronary plexus.

The above description must be taken as an average arrangement, since *there are considerable variations.*

The *propagation* and *conduction* of the *heart's contraction* is now known to be the function of a special tract of heart muscle (fig. 2173) which starts at the *sino-auricular node*, a small thickening in the wall of the right auricle just below the entrance of the superior vena cava. This node is regarded as the pace-maker in which the heart's beat originates. From it rather indefinite muscular fibres can be traced to a well-defined *auriculo-ventricular node* (of Tawara), situated in the wall of the right auricle a little below the mouth of the coronary sinus. The node of Tawara forms the starting point of the *auriculo-ventricular bundle* of His,

by which the contraction wave is conducted from the auricles to the ventricles. This bundle runs forward just below the thin (membranous) part of the interventricular septum, and shortly divides into right and left fasciculi, which enter

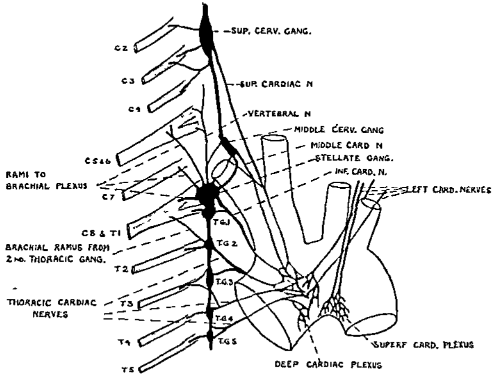

Fig 2172.—THE CARDIAC PLEXUS AND ITS CONNECTIONS.

the septal wall of the corresponding ventricle, and blend with the sub-endocardial muscle-fibres of Purkinje. The whole of this conducting or Hissian system is of vital importance, and it must be carefully avoided in all operative procedures on

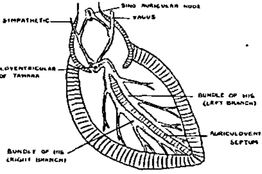

Fig 2173.—THE CONDUCTING MECHANISM OF THE HEART.

the heart. Disorders of this system are often caused by coronary occlusion, and manifest themselves in various disturbances of the cardiac rhythm.

Extrinsic Mechanism (fig. 2172). The heart muscle and the coronary vessels are controlled by *efferent* or *motor* nerves which reach the cardiac and coronary plexuses from the sympathetic and from the vagus. The more conspicuous *cardiac branches of the sympathetic* come from the superior, middle and inferior

cervical ganglia, in the form of three distinct nerves, the superior, middle and inferior cardiac. These nerves consist of post-ganglionic neurones, and since the cervical sympathetic ganglia have *no central connections, except through the stellate* ganglia, the pre-ganglionic motor neurones must come from the upper five or six thoracic white rami and reach the cervical sympathetic chain via the thoracic chain and the stellate ganglia.

Recent work (1927–1933) by White and others, however, has shown conclusively that these cervical cardiac nerves are not the only sympathetic nerves which reach the heart, but that there is a second and equally important group of post-ganglionic fibres which supplies the cardiac plexus, and which comes from the upper four or five thoracic sympathetic ganglia. This discovery is of the utmost significance in the surgical treatment of angina pectoris, and will be further alluded to.

In addition to motor or efferent fibres, the cardiac sympathetic nerves also carry *sensory* or *afferent* fibres, which start as typical sensory nerve-endings in the pericardium, epicardium and heart muscle, and also in the adventitia of the aorta and coronary vessels. It should be noted, however, that there are no sensory paths above the middle cervical ganglion, and that therefore the superior cervical ganglion and its superior cardiac branch are purely motor.

The cardiac branches of the *vagus* are two or three in number. Those on the right side arise from the nerve itself, but at least one of the left cardiac branches comes from the left recurrent laryngeal as it winds round the arch of the aorta. In some animals, and sometimes in man, the *afferent* fibres of the vagus form a separate nerve—the *cardiac depressor* of Cyon and Ludwig, but very often the afferent depressor neurones run in the same cardiac branches as the efferent or motor fibres.

FUNCTION OF THE CARDIAC NERVES

The *vagus* is the *inhibiting* nerve to the heart. By its afferent or depressor fibres it can produce a generalised reflex vasodilatation with a fall of blood-pressure. Its action on the coronary flow cannot be considered as definitely settled. On the one hand, there is evidence that it constricts the coronary arteries, but, on the other hand, it would appear that stimulation of the vagus increases the coronary blood-flow. It is probable that this last effect is controlled by the rate and muscular activity of the heart, rather than by the size of the coronary vessels.

The *sympathetic* is the cardiac *accelerator*; it is probably vasodilator to the coronary vessels; and it is also the *sensory* nerve of the heart.

There appear to be several sensory mechanisms in the regulation of cardiac activity. Leriche and Fontaine demonstrated the presence of an automatic mechanism, by which sensory stimulation of the endocardium and pericardium evokes depressor effects, while stimulation of the aortic region produces pressor effects. The *pain sensibility* of the heart, the aorta, and the coronary vessels is intense, and seems to depend entirely on the sympathetic. According to Leriche and Fontaine the greater part of this pain sensibility can be abolished by removal of the left stellate ganglion, while a bilateral stellectomy completely removes cardiac sensations of pain. On the other hand, White in 1935 stated that bilateral stellectomy results in a partial reduction of cardiac sensibility, and that complete abolition of sensation can only be obtained by resection of the upper

four thoracic ganglia. White's assertion is supported by the anatomical connections of the cardiac plexus (see page 3943), and is of obvious importance in its bearing on the surgical treatment of angina.

Apart from the local or sympathetic sensory mechanism, cardiac pain can also be of the *referred* type, being felt in the skin over the precordial region and the inner surface of the arm. This pain can be abolished by local anæsthesia of the skin areas, but is only of secondary importance in painful lesions of coronary origin.

Another nerve structure which has a definite influence on the heart is the *carotid sinus plexus*, situated round the bifurcation of the common carotid, and receiving afferent fibres from the vagus and efferent ones from the superior cervical sympathetic ganglion. Heymans and others (quoted by White) have shown in 1933 that this small plexus is a highly specialised centre which can affect the heart rate, blood-pressure and respiration. Resection of this plexus has been known to cure attacks of recurrent syncope.

PERICARDIUM AND MECHANISM OF HEART TAMPONADE

The pericardium is a triple-layered sac which surrounds the heart somewhat loosely. The outer layer, or *fibrous pericardium*, is composed of very dense fibrous tissue and is funnel shaped ; its upper narrow end is prolonged from the base of the heart on to the great vessels, while its lower wide end is open and is firmly attached by its rim to the central tendon of the diaphragm, which thus comes to form the actual floor of the pericardial chamber. The extent to which the fibrous pericardium ensheaths the great vessels is as follows : the aorta as far as the origin of the innominate, the pulmonary artery to its bifurcation, and the superior vena cava as far as the entrance of the azygos major vein ; the inferior vena cava in its short thoracic part is entirely intrapericardial, but the pulmonary veins pierce the pericardium immediately before they enter the left auricle. The external relations and surface markings of the pericardium have been considered already (see page 3936).

The inner two layers form a typical closed serous sac—the *serous pericardium*. The outer or *parietal layer* is the thicker of the two, and is closely adherent to the fibrous pericardium and the upper surface of the tendon of the diaphragm, both of which it lines. The inner *visceral layer*, or *epicardium*, is very thin and closely invests the heart and the intrapericardial part of the great vessels. It is intimately connected with the cardiac muscle, except along the auriculo-ventricular and interventricular grooves, where the coronary vessels and a variable quantity of fat intervene. The serous pericardium normally contains about 25 cc. of clear fluid.

The parietal and visceral layers of the serous pericardium meet on the great vessels, at the limits of their investment by the fibrous pericardium. Thus are formed lines of reflection of the serous pericardium, which are known as *mesocardia*, and of which there are two—the arterial and the venous. The *arterial mesocardium* forms a common sheath for the aorta and pulmonary artery, while the *venous mesocardium* includes the four pulmonary veins and the two venæ cavæ. Between the two mesocardia is a tunnel leading from one side of the serous sac to the other; this is the great *transverse sinus* of the pericardium (fig. 2174), and it has the aorta and pulmonary artery in front and above it, and the auricular part of the heart with the great veins behind and below it. The importance of the transverse sinus will be appreciated when methods of temporary arrest of

the heart's action come up for consideration. There is a second or *oblique* pericardial sinus, which is a recess in the venous mesocardium, but this is of no special surgical significance.

Cardiac tamponade is the name given to compression of the heart by accumulation of fluid in the pericardium. It is the chief morbid factor in cardiac injuries, and until it was thoroughly understood no advance was possible in the treatment of these injuries. Although Morgagni first realised the danger of an increase in intrapericardial pressure in 1761, it was not until Rose fully investigated the question and coined the word " Herz-tamponade " in 1884, that its mechanics were properly appreciated.

The morbidity of tamponade depends on the non-distensibility of the fibrous pericardium, except to a very slow rise of pressure. As blood begins to accumulate in the pericardium, sufficient pressure is rapidly developed to produce obstruction of the veins entering the heart, with the result that there is a fall in the arterial blood-pressure, and a rise in the venous blood-pressure. Further tamponade causes a fall of the pulse-pressure, a rise of the pulse-rate, and certain symptoms of

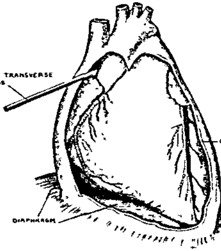

Fig 2174 —THE PERICARDIUM
(*After Buchanan's "Anatomy."*)

which cyanosis is the most prominent. Very soon the resistance of the rigid fibrous pericardium exceeds that of the muscular cardiac wall, and the accumulation of further blood makes room for itself by squeezing the heart and diminishing the capacity of its chambers. Furthermore, when the intrapericardial pressure equals or exceeds the venous pressure, the heart fails to fill, and its output becomes still more seriously endangered.

Such are the mechanics of *acute tamponade.* Owing to the severe embarrassment of the heart, resulting from the diminution of its capacity and of the amount of blood at its disposal, only a moderate quantity of fluid (200–250 cc.) will suffice to cause fatal cardiac compression. The rapidity of tamponade is an important factor, for if the accumulation of fluid is slow enough the fibrous pericardium will distend until the limit of its elasticity is reached. Under such circumstances the condition is a *chronic tamponade,* and more than two litres of fluid may collect before the intrapericardial pressure reaches the venous pressure, and serious cardiac compression begins. It must be understood that chronic tamponade never occurs in connection with heart wounds, although it may be an important factor in pericardial effusion, and in hæmopericardium from a constitutional disorder such as scurvy.

Wounds of the Heart

INTRODUCTION

Unquestionably the best results of cardiac surgery attend the suture of traumatic wounds of the heart. It was with this operation that heart surgery was born forty years ago, and there can be nothing more dramatic in the whole sphere of the science of healing than the saving of a life, otherwise doomed to certain death, by this most recent and brilliant achievement of the surgeon's art.

The *history* of the surgery of cardiac injuries is of considerable interest. Injuries of the heart were thought to be invariably fatal until Wolf in 1642 first described a healed heart wound in a deer killed in the chase. In 1882 Block reported several recoveries after suture of cardiac wounds in rabbits, while in 1895 Del Vecchio showed healed wounds in the hearts of dogs, also after suture. Yet in 1883 the great Billroth stated that " the surgeon who attempted to suture a wound of the heart would lose the respect of his colleagues." In 1895 Cappelen of Christiania was bold enough to suture a wound of the human heart for the first time. The attempt was unsuccessful, and in 1896 Stephen Paget made the following ponderous statement: " The surgery of the heart has reached the limit set by nature to all surgery; no new discovery can overcome the natural difficulties that attend a wound of the heart." Later in the same year Rehn of Frankfurt (September, 1896) first successfully sutured a wound of the human heart! Ten years later Rehn was able to collect 124 cases of heart suture with a 40 per cent recovery. Since that time the cases published and the ratio of recoveries have both risen very considerably. In 1920 Tuffier collected 305 cases with a recovery rate of over 50 per cent, while Ballance analysed 152 cases operated on between 1912 and 1920 (many of them in the Great War) and found that 68·4 per cent recovered. Finally, Cutler reported 28 cases of heart suture between 1920 and 1926, with recovery in no less than 78·6 per cent.

The suture of a wound of the heart must now be regarded as an established surgical operation of very definite life-saving value, and one which every practising surgeon should be prepared and equipped to perform.

MORBID ANATOMY AND CAUSATION

A large heart wound which communicates freely with the exterior, the mediastinum, or the pleura, will prove fatal from hæmorrhage long before surgical aid can be obtained. The cases which can be saved are

those with small wounds, which very soon lose their communication with the exterior by clotting, or by shifting of the tissue planes over the heart owing to changes of posture after the injury, or because the wound of the pericardium is valvular. Such a patient does not die from hæmorrhage, but from the accumulation of blood trapped in the pericardium, and from the *cardiac tamponade* or compression caused thereby. The mechanics of heart tamponade and the factors responsible for its lethal effects have already received sufficient consideration (see page 3945).

Heart wounds of this character are usually inflicted by stabs with various sharp weapons, by bullets, or by shrapnel. The point of entry is mostly to the left of the sternum, in the third, fourth or fifth interspace, and the left ventricle is the part most often injured. The right ventricle is the second most common site of injury, the skin wound being either to the left or to the right of the sternum. The auricles are less frequently involved, but many cases are reported of injuries of one or other of them. Wounds of the posterior aspect or base of the heart are only rarely amenable to surgical treatment. It should be observed that a very small wound of the heart may cause fatal tamponade, and that it may do so without penetrating into a cardiac chamber. Cutler records a fatal tamponade after diagnostic needling of the pericardium, the needle having pricked a coronary vein. Several similar cases have been published.

DIAGNOSIS

Accurate and timely diagnosis of a heart wound is of the utmost importance. Exploratory operations without adequate reason, and delay in the presence of strong evidence of cardiac involvement, are to be equally deprecated. There are three factors which are sufficiently typical to be of real diagnostic value : (1) an external wound, (2) a short free interval following its infliction, and (3) the symptoms and signs of tamponade.

(1) *The External Wound.* A skin wound near the edge of the sternum and between the second and sixth costal cartilages should suggest the possibility of heart injury, particularly if inflicted with gun-shot, or with a weapon sharp enough and long enough to penetrate the necessary distance. The actual position of the skin wound, although of obvious importance, may be deceptive, unless the position of the patient and the trajectory of the missile, or direction of the stab, are either known or can be reconstructed.

Immediately after the wounding there is usually very brisk bleeding, which is of diagnostic importance, especially if it occurs in spurts coinciding with the pulse ; but it should be known that a severed

internal mammary artery may bleed severely enough to resemble a heart injury at first sight. Blood mixed with foam suggests lung injury, but it may also come from the heart, having been churned up in the pericardium.

In rare cases the instrument of trauma, e.g. a dagger, may still be *in situ*, plugging the wound and perhaps preventing hæmorrhage. Such an instrument may oscillate with the heart beat. It should not be disturbed until the patient reaches the operating table, as its premature withdrawal may prove fatal. A famous example of this was supplied by the case of the Empress Elizabeth of Austria, who died in 1898 after the withdrawal of a file from her heart.

(2) *The Free Interval.* This is very short, lasting about ten minutes on the average. Apart from wound pain, the patient may complain of very little. Very soon the external bleeding diminishes or may cease completely. Blood begins to accumulate in the pericardium, and the stage of tamponade is ushered in.

(3) *The Tamponade.* The symptoms of cardiac compression appear, often somewhat abruptly, at a short but variable interval after the injury. The length of this interval, the degree of tamponade, and the rate at which it develops, depend on the presence or absence of an outlet through the pericardial wound; the size and patency of the outlet are the determining factors, and it matters little whether the communication is with the exterior or with a neighbouring body cavity.

The symptoms and signs of heart tamponade are of the greatest importance, as it is on them that the diagnosis of a heart wound mainly depends. At first the patient is restless and frightened, and feels chilly, clammy, and thirsty. Soon the extremities become very cold, a cold sweat covers the body, respiration becomes sighing and irregular, and the colour changes to a rather suggestive combination of extreme pallor and cyanosis. The pulse becomes weaker and weaker, or comes and goes. The peripheral arteries lose their pulse quite early. The arterial blood-pressure sinks rapidly, but the venous pressure rises and the external jugular and other veins may become very prominent. The collapse increases and the patient sinks into unconsciousness.

Examination of the heart reveals that the sounds are indistinct and muffled and become more so every few minutes. The cardiac dullness may increase a little, but this is of questionable diagnostic value. Equally questionable is the wisdom of an X-ray examination; definite information is only likely in cases which are clinically obvious, and the time can be ill afforded.

Briefly, the signs of greatest diagnostic value are: (1) a wound likely to penetrate into the heart, (2) a short symptomless interval, (3) early loss of the peripheral pulse, (4) extreme pallor and cyanosis, (5) prominent veins, and (6) muffled heart sounds.

TREATMENT

Operation at the earliest moment possible is the only hope of saving life, and recent statistics (see page 3946) prove that in cases which survive long enough to reach the operating table this hope is very considerable (more than 70 per cent). The factors which determine success, and therefore influence *prognosis*, are: (1) the time between injury and operation, (2) the size, site and nature of the wound, (3) the presence or absence of other serious visceral injuries, (4) the physical condition and age of the patient, and (5) the skilfulness, coolness, speed, care and judgment of the surgeon.

There can be no question of selection of cases. Every patient who reaches the theatre with the least evidence of cardiac function should be operated upon, as even in the most desperate case the compressed heart may revive immediately the pericardium is opened.

The essential step of the operation is the closure of the heart wound by suture. The closure must be effected in a veritable swirl of blood, without interfering with the circulation through the heart chambers and without obstructing the coronary vessels. Adequate *exposure* is almost as important as the saving of time, for when the pressure is released by incising the pericardium, the heart revives astonishingly, and the patient may bleed to death in a few minutes, and even before the actual wound is found.

The *approach* to the heart is, therefore, of the greatest importance. There are two main routes—the trans-sternal and the parasternal. The *trans-sternal approach* is a long and shock-producing operation, but it ensures the best exposure and gives a reasonable chance of avoiding injury to the pleura. The *parasternal approach*, of which there are several varieties, is a more rapid and much safer procedure, but it does not afford the same exposure of the heart, and is likely to enter the pleura. In spite of these drawbacks, however, the parasternal approach is the one recommended and employed for most cases of heart wounds. Through it the left side of the heart (the most common site of injury) can be reached with ease, and any associated injury of the lung or pleura treated; even injuries of the right heart can be dealt with by employing the wider type of parasternal exposure. We propose, nevertheless, to discuss all established routes of approach, as

even the one least favoured may have special application to a particular case.

In the actual surgical management of a heart wound we may distinguish five steps: (1) the preparation, (2) the anæsthetic, (3) the approach, (4) the cardiac manipulation and suture, and (5) the after-treatment.

1. *The Preparation.*

The patient should be rushed to the theatre on admission and kept warm. All possible time must be saved in preparation of the theatre and patient, sterilisation of instruments, and securing the attendance of a competent surgeon. Intravenous fluid and transfusion are definitely contra-indicated at this stage, as they tend to aggravate the mechanical difficulties under which the heart is labouring.

2. *The Anæsthetic.*

The operation can often be started without anæsthesia, the patient being profoundly unconscious. Advantage should be taken of this stage to insert a tube into the trachea. Soon after the pericardium is opened, however, consciousness may return, and a rapid induction becomes necessary. By far the best and safest anæsthetic is intra-tracheal gas and oxygen. A positive-pressure apparatus should be available, especially when the parasternal route is employed and a large trans-pleural opening may be necessary.

3. *The Approach.*

(*a*) *Trans-sternal Route* (thoraco-abdominal route of Duval Barasty). A mid-line incision is made from the level of the second rib to near the navel (fig. 2175). The linea alba is divided, the ensiform cartilage is excised, and the diaphragmatic attachments are freed as far as necessary. The pleura is pushed away from under the sternum with the finger, a spatula pushed up to protect the soft parts, and the sternum split with a circular saw as far as the second space, where it is cut across transversely. At this stage care must be taken to avoid the internal mammary artery. Section with the circular saw assists careful coaptation later, and so avoids the terrible pain caused by rubbing together of the two halves of the sternum when the division is made with shears. Retractors are now inserted to pull apart the two halves of the sternum, and the two pleuræ are deliberately wiped away to expose the front of the pericardium. The peritoneum, the anterior part of the diaphragm, and the anterior pericardium, are now divided with scissors from below upwards. Finally, the inferior pericardium and left cupola of the dia-

phragm are divided backwards and to the left for a short distance, and thus an extremely full exposure of the heart is obtained. At the end of the operation the two halves of the sternum are wired together, drill holes having been made prior to its division.

(*b*) *Parasternal Route.* There are at least four distinct types of the *left parasternal approach*: the flap or trap-door method, the rib-resection method, the intercostal method, and the Spangaro approach.

(i) *Flap Method.* This is known as Kocher's approach and was in

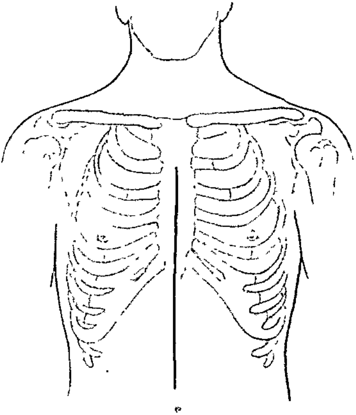

Fig 2175.—Incision for Duval Barasty trans sternal approach

general use till recently. A flap or trap-door is turned out, consisting of the whole thickness of the chest wall, and including the third, fourth, fifth and sixth left cartilages. The cartilages should be lifted off the pleura with great care to avoid injury of the latter. The pleura is either pushed aside or opened, according to the degree of exposure required. At the end the whole-thickness flap is replaced and sutured in layers.

(ii) *Rib Resection* (fig. 2176). This is a modification of the above method, in which various lengths of costal cartilages and ribs are removed.

(iii) *Intercostal Method.* A long major thoracotomy incision is made along the fourth left intercostal space, the pleura divided, and an adequate exposure obtained by wide retraction with rib-spreaders.

(iv) *The Spangaro Method* (fig. 2177). Undoubtedly the best of the parasternal approaches, this is quick, simple, gives a fair exposure, and renders air-tight closure of the thorax easy. In brief it may be termed an *intercosto-chondrotomy*. A long incision (from sternum to anterior axillary line) is made through the intercostal space nearest the wound (usually the 4th space, but in high wounds the 3rd or even the 2nd—

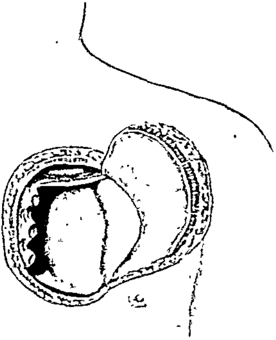

Fig 2176.—PARASTERNAL APPROACH WITH RIB RESECTION.

see fig. 2178). A second incision is made along the sternal edge, making the skin incision T-shaped. The sternal attachment of as many costal cartilages as necessary—at least one, but preferably two above and below the incised space—is separated from the sternum (fig. 2178). The internal mammary artery is ligatured above and below, the pleura divided, and a rib-spreader applied. The lung is packed off and the pericardium identified and incised. Good exposure is obtained only of the left ventricle and auricle. To improve the exposure the adjacent part of the sternum may be removed by the gouge or nibbler, or one cartilage with part of its rib may be resected. At the end of the operation air-tight closure of the thorax can be obtained by tying together the two

ribs which margin the rent in the pleura ; this is much easier and more effective than any attempt to suture the pleura.

(v) *Bilateral Parasternal Approach* (see fig. 2179). This was suggested and employed by Beck as an alternative to the Duval Barasty trans-sternal route, when very free exposure of the heart is desirable (e.g. for wounds of the right side or back of the heart). Flaps are raised to each side of the sternum, the 3rd, 4th, 5th and 6th cartilages are removed on both sides, care being taken not to wound the pleura, and the adjacent parts of the sternum are gouged away. The internal

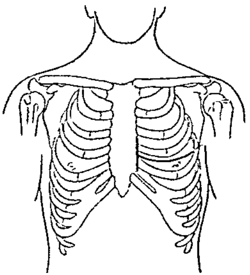

Fig. 2177.—Incision in Spangaro approach. (*Modified.*)

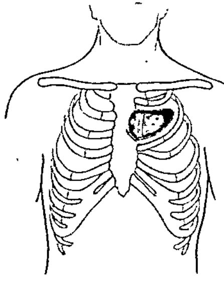

Fig. 2178.—The Spangaro approach. (*After Arthur M. Shipley.*)

mammary vessels are tied above and below and the pleuræ pushed out of the way. This approach gives a beautiful exposure of the whole heart.

Choice of Approach. When there is good reason to believe that the wound is in the *left side of the heart* one of the left parasternal methods should be employed. The Spangaro approach is the best of these, and is particularly indicated when there is an associated injury of the lung. If the surgeon particularly desires to *avoid opening the pleura* he must choose between the Duval Barasty trans-sternal approach, which gives the best exposure but is also the most dangerous method, and the flap method with resection of costal cartilages, which is very much safer but provides a more limited exposure. It would be most reasonable to start with a left parasternal chondrectomy, to improve exposure by removing the adjacent part of the sternum, and then, if it is thought that more room will be needed, to repeat the procedure on the opposite side ; all this must be done *before* the pericardium is opened.

Many wounds of the *right side of the heart* can be approached by a

left parasternal route, but in cases likely to be difficult, and in injuries of the *back of the heart*, the surgeon must choose between the trans-sternal route and Beck's bilateral parasternal approach.

4. *The Heart Suture.*

The exposure of the wounded heart is only one half of the operation. The other and more troublesome half is finding and closing the wound in the midst of hæmorrhage, which, as soon as the pericardium is opened, becomes imminently dangerous. This is where the deliberate and cool surgeon, who can preserve his equanimity at a critical moment, is a great asset.

Whatever method of approach is used, it ends with the exposure of the pericardium. This will be obviously distended and separated from

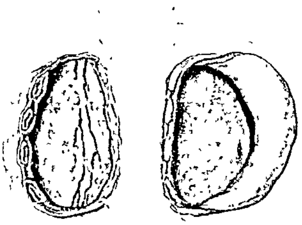

Fig. 2179.—Bilateral parasternal approach. (*After Claude S. Beck.*)

the heart by a lake of blood. The wound in the pericardium is usually found without difficulty, and it must be enlarged quickly and sufficiently to enable the surgeon not only to find and control the cardiac wound, but also to control the beating heart itself. A variable quantity of accumulated blood will be encountered on opening the pericardium; this is mopped away or removed with a sucker. A finger should be passed behind the heart to remove clots. The heart now begins to beat vigorously, and its wound becomes apparent by the ejection through it of big, and sometimes alarming, spurts of blood.

The loss of blood must be immediately controlled. *If the cardiac wound is small* this can be done by applying a finger to it, but the application must be *very gentle*, as the heart muscle is friable and the wound will be made larger if any force is used. The surgeon now inserts

a suture under the finger, this being left untied and used for hæmostasis and traction (fig. 2180). If there is any difficulty in getting to the wound, a *traction suture* should be passed through the thick *apex* of the heart, and with this the assistant can steady the organ, and also pull it or rotate it to bring the wound into a better position for suture (e.g. in wounds of the right ventricle or auricle).

The actual *suture* of the heart should be done with thin black silk or chromic catgut, threaded on small curved round-bodied needles, on a needle-holder. They should all have been previously prepared and threaded, and they must be inserted and tied very gently. Two or three interrupted sutures suffice to close most cardiac wounds which reach the surgeon, but great care is needed to avoid injury to or inclusion of a coronary vessel.

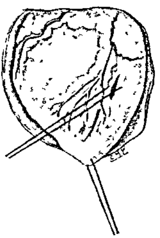

Fig 2180.—Traction and control heart sutures.

With a *large heart wound* the finger is useless for the arrest of hæmorrhage, and it may be necessary to compress the heart base. Recently (December, 1935) Kiser has shown that, while the heart will not tolerate compression of the great arterial trunks (aorta and pulmonary artery), it can survive after compression of the great veins entering it, provided this is not prolonged for more than two minutes. On the human heart this method of temporary arrest is best effected by compressing the venous side of the heart base between the third finger of the left hand, which is passed into the transverse sinus of the pericardium (see page 3944), and the fourth and fifth fingers, which are passed in front of the inferior vena cava; this manœuvre leaves the thumb and index finger free for holding and steadying the heart. One or two control mattress sutures are now passed through the wound and further hæmorrhage is arrested by traction on them, while the final sutures are inserted and tied. Compression of the base must be relaxed after a minute, for a few seconds, in order to allow some blood to reach the aorta and coronary arteries. The mortality of heart wounds which require compression of the base is bound to be high.

At or before the conclusion of the suture an injection of 1 cc. of 1 in 5000 adrenalin may be made into the cardiac muscle if the heart is beating feebly, while cardiac massage should be tried if it actually stops.

After dealing with the heart, the pericardium is cleansed with saline and sutured. When absolute hæmostasis has been obtained the

pericardial suture may be completed, but if there is any doubt the lower corner of the pericardium must be left open for drainage, and a tube inserted down to it (but never into it) for 48 hours. Any associated injury of the lung is now sutured with gently inserted mattress sutures, and the pleura, if opened, is closed in an air-tight manner; in the Spangaro approach this is done by tying the ribs together over the pleural rent. When positive-pressure anæsthesia has been employed collapse of the lung will have been prevented, while if moderate collapse has been encouraged for the purpose of improving exposure the lung should be re-expanded at the end of the operation; otherwise, the air in the pleura must be removed by aspiration after the chest is closed. Finally, the thoracic wall is sutured in layers.

In a recent article, Mayer (*Surg., Gyn. and Obst.*, May 1936, 852) advises against external drainage after operations for heart wounds. Instead, he recommends internal drainage by leaving a wide communication between the pericardium and pleura. If much fluid accumulates in the pleural cavity, it may be removed by aspiration.

5. *After-Treatment.*

Post-operative care is important; quiet, warmth and anti-shock measures are always necessary. One of the most troublesome early complications is delirium due to cerebral anæmia; this is common and may need a good deal of morphia for its effective control. Pleural effusion is almost inevitable if the pleura has been opened, and this will require repeated aspiration. The oxygen tent has proved very valuable in such cases. Occasionally the pleurisy terminates in empyema, which may necessitate drainage.

Surgery of Suppurative Pericarditis

PATHOLOGY

Acute pericarditis is rarely a primary lesion; it is mostly seen as a *complication* of other infective conditions. Perhaps its commonest causes are *pneumonia* and *empyema*, but it may also complicate *rheumatic carditis* with *secondary infection*. Another fairly frequent cause is *pyæmia*, especially when this is a sequel of acute *osteomyelitis*. Rarely, infection may be direct, through external *trauma*. In a somewhat different category is *tuberculous* pericarditis, which may be either primary, or secondary to phthisis or pleurisy.

The *morbid anatomy* is similar to that of suppurative inflammation of any serous sac. The serous pericardium shows the usual changes of acute inflammation, and is filled with a serous exudate which becomes

progressively more purulent. When the accumulation of fluid is rapid the principal morbid factor is *tamponade*, although it must be understood that a larger quantity of fluid will be needed to compress the heart than in cases of wounding, as the accumulation is bound to be much slower, and the fibrous pericardium will give way to some extent. With a more chronic exudation the pericardium will enlarge to the limits of its elasticity, and tamponade will be a late and relatively unimportant feature. In such cases the principal lethal factor is *infection* of the pericardium, heart and other tissues.

DIAGNOSIS

This, of course, belongs to the province of the physician, but from the large number of undiagnosed cases which reach the post-mortem room it would appear to be a difficult matter. Together with the general symptoms of a severe infection, acute cases may show a friction rub, followed by the signs of enlargement of the pericardium (increased dullness, muffled heart sounds, etc.), and perhaps by the clinical features of heart tamponade (see page 3946). An *X-ray examination* is of real service; it shows marked enlargement of the heart shadow in all directions, but particularly in the transverse diameter, while pulsation is barely visible, and may be absent. *Diagnostic puncture* should only be employed when absolutely necessary, as it is definitely dangerous. Several cases are recorded where the needle pricked a coronary vessel or a thin part of the heart wall, causing a fatal tamponade from hæmopericardium.

SURGICAL TREATMENT

The best hope of saving life lies in *drainage* of the pericardium in the most dependent position. In the approach to the pericardium it is best to avoid the diaphragm, and to reach it by a trans-sternal or a trans-chondral route. All drainage operations (pericardiotomy) are based on the triangular area behind the lower and left part of the sternum and the adjacent parts of the fifth and sixth left costal cartilages, where the pericardium is uncovered by the pleura. For a full description of this "triangle of safety" the reader is referred to page 3936, but it should be remembered that owing to the bulging of the distended pericardium the triangular area tends to be somewhat larger than normal.

Trans-sternal pericardiotomy, by trephining the sternum just above the ensiform cartilage, was first suggested by Riolanus as long ago as 1648. It has fallen into disuse because the approach is too cramped

to permit introduction of the finger for the purpose of freeing adhesions.

The *trans-chondral approach* gives an excellent exposure, and can be effected under *local anæsthesia.* A 2-3-inch incision is made along the left edge of the sternum and the 7th costal cartilage, the 6th and 7th cartilages are removed sub-perichondrally, and the internal mammary vessels pushed aside or tied. The pericardium now comes into view. One difficulty of the operation is that the beating apex of the left ventricle always seems very near, and it is impossible to know how thick the pericardium is, and whether it is adherent or not. Another difficulty is that the pericardium tends to fall back out of sight after the fluid has been let out. For these two reasons the pericardium should always be picked up with two traction sutures, the fold thus produced

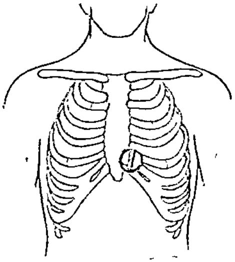

Fig. 2181.—Approach for pericardiotomy. (*After Arthur M. Shipley*)

carefully palpated to estimate its thickness, and the incision made between the sutures. A finger is then inserted and any recent adhesions are gently broken down. After the fluid has escaped, the pericardium is washed out with saline, and a drain applied just to (but not through) the hole in it. Dakin's solution and other irritating fluids should not be used for the irrigation as they are liable to cause pericardial adhesions.

Recently, Shipley has advocated a *combined trans-sternal and trans-chondral approach* (fig. 2181). The sternum is trephined a little to the left and just above the ensiform, the opening enlarged to the left edge of the sternum, and the adjacent parts of the 6th and 7th cartilages cut away. This approach gives a very free exposure.

After-Treatment consists in securing maximum drainage by employing the ventral position for short periods. Pockets of pus can be reached by inserting

a catheter through the wound. Pericardiotomy usually gives great and immediate relief, but the pus discharge is likely to continue for a long period. Pericardial adhesions are a possible sequela and should be watched for.

Some years ago (1930) Beck and Cox drew attention to the cardiac embarrassment which might be caused by the loss of negative pressure following *open pericardial drainage. They showed that after pericardiotomy there is a fall* in arterial pressure, a rise in venous pressure, and a diminished cardiac output. It may be that *closed drainage* will prove the best treatment for pericardial effusion, and that it will be followed by improved results.

Surgery of Chronic Adhesive Pericarditis

INTRODUCTION

No literature of a great surgical achievement could make more fascinating reading than that which describes the advent and elaboration of operative treatment in chronic pericarditis. That the various operative procedures were first conceived and suggested by physicians is a clear indication of the helplessness of our medical colleagues before this merciless disease, which slowly but surely cripples the heart by anchoring it to the chest wall or some other unyielding neighbour, or equally surely shackles and strangles it by a massive pericardial fibrosis. It is to the credit of surgery that it responded to the call of its sister science, and that surgeons appeared with the audacity and skill required to solve unfamiliar problems, and to achieve a measure of success.

Of the numerous contributions which have recently been published on this subject, the most useful and comprehensive is that of Lenormant and Leriche, which was written in 1932, and of which free use has been made in the preparation of this section. Among other excellent articles which have been utilised is one written by Cutler, and another by Shipley, also appearing in 1932. Great credit must also be given to Beck and Griswold, who investigated the morbid changes of this disease in dogs, in whom they produced a constrictive pericarditis by irrigating the pericardium with Dakin's solution.

PATHOLOGY

Pericardial adhesions are a common post-mortem finding, but a large majority of them are of little clinical significance. Those that interest us are the relatively rare ones which cause progressive interference with the heart's action. Such cases of adhesive pericarditis are seen mostly in childhood or adolescence, and the great bulk of them are caused by either *rheumatism* or *tuberculosis*. Among less common

causes are suppurative pericarditis, injury with hæmopericardium, pleuro-pulmonitis, and mediastinitis.

Adhesive changes involving the pericardium may be partial or diffuse. They may be limited to the serosa, or they may spread beyond this to the myocardium, the fibrous pericardium, or the extrapericardial structures. They may scarcely hamper the heart, they may disable it by fixing it to the chest wall or diaphragm, or they may cripple it completely by encasing it with a thick mass of constricting fibrous tissue. It is therefore obvious that several distinct pathological and

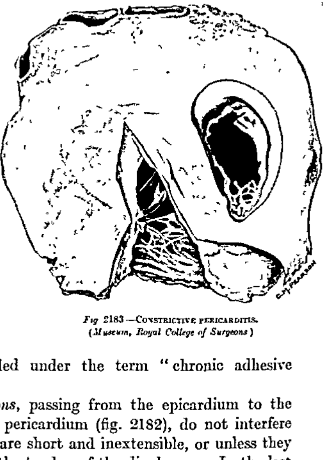

Fig 2183.—Constrictive pericarditis.
(*Museum, Royal College of Surgeons*)

clinical pictures are included under the term "chronic adhesive pericarditis."

Single or *partial adhesions*, passing from the epicardium to the serous lining of the fibrous pericardium (fig. 2182), do not interfere with the heart, unless they are short and inextensible, or unless they anchor the apical region to the tendon of the diaphragm. In the last case serious cardiac trouble may be caused since the heart is dragged on by each respiratory movement.

A more *complete adhesive process* obliterates the serous space and fixes the fibrous pericardium to the heart. As a rule, some part of the pericardial cavity is left unobliterated, especially on the right side of the heart, and may enclose a serous or purulent fluid. Once initiated,

the adhesive fibrosis does not limit itself to the pericardium, but tends to spread beyond it, either to the mediastinal cellular tissue, or to the sub-epicardial heart muscle. Hence, we are able to distinguish two more or less distinct varieties of *diffuse adhesive pericarditis*: (1) the external or centrifugal type, which may be termed *mediastino-pericarditis*, and (2) the internal or centripetal type, which constitutes the *constrictive pericarditis* of English writers, and the *pericardite calleuse* of French writers.

Adhesive mediastino-pericarditis is the classic type, in which adhesions and fibrosis not only obliterate the pericardial space, but also extend beyond the fibrous pericardium, and fix it to the pleura, diaphragm, sternum and ribs, and sometimes even to the spine. It is obvious that such fixation of the heart is bound to interfere with its mobility and contraction, and that it must ultimately lead to progressive cardiac failure and death. This is particularly the case when the heart is anchored to the rigid anterior wall of the chest. Continuous shortening of the anterior mediastinal adhesions exercises progressive traction on the heart, which exhausts itself by pulling against the unyielding parietes. At the same time, the front margins of the lungs, which normally move in to occupy the space created by the systolic retraction of the heart, can do so no longer, since they also share in the adhesive process. There is thus produced a profound interference with cardiac systole, and finally systolic retraction becomes impossible and the heart fails.

Constrictive or *callous pericarditis* is more common and even more serious than the above, although our knowledge of its pathology and clinical significance is more recent. In this, the morbid changes mainly affect the epicardium, and consist briefly of a massive fibrosis immediately surrounding the heart. This becomes immured in a great mass of fibrous tisue (fig. 2183), perhaps a quarter of an inch or more in thickness, which is rigid and pitilessly retractile, and which may become almost cartilaginous in consistency. Sometimes the fibrosis is more marked round the right heart, sometimes round the left. The sclerosis starts in the epicardium and in the intrapericardial adhesions, but later it invades the heart muscle itself, into which it may spread very deeply; calcification is not uncommon in the masses of scar tissue.

The heart is imprisoned in its fibrous armour, the progressive contraction of which literally strangles it. Diastole is the first cardiac function to be interfered with. The thick wall of the left ventricle resists this compression for a time, but the thin-walled auricles feel it very early. Pulmonary stasis results from interference with left

auricular diastole, while stasis in the territories of the superior and inferior venæ cavæ occurs, partly because diastole of the right auricle is impeded, but also because the actual mouths of the cavæ are caught in and compressed by the encasing fibrous mass. Pulmonary venous stasis is thus evidence of constrictive pericarditis of the left heart, while systemic venous stasis shows that the right heart is involved.

The interference with cardiac diastole becomes greater and greater, the venous stasis more and more marked, and progressive heart failure is the inevitable result. It may be accelerated by the myocardial fibrosis, or even by an actual myocardial ischæmia due to compression of the coronary vessels by the pericardial fibrous masses.

Although these two types of adhesive pericarditis produce such very distinct and different morbid changes, in actual fact they frequently coexist in the same patient. Depending on the nature of the combination, and on the degree to which one type predominates over the other, both the pathological and the clinical picture of the disease will obviously show considerable variation.

DIAGNOSIS

It follows from the last paragraph that we may expect two types of clinical syndromes, one produced by adhesions between the pericardium and its surroundings (mediastino-pericarditis) and the other by constricting or callous pericarditis.

Mediastino-pericarditis is associated mainly with parietal symptoms. The apex beat becomes fixed and does not move with changes of position. There may be very marked systolic retraction of the chest wall, both in the precordial region and posteriorly at the vertebral ends of the left 9th, 10th and 11th ribs (Broadbent's sign). The precordial region may also show a diastolic rebound. *Adhesions to the diaphragm* are responsible for the so-called *pulsus paradoxus* of Kussmaul, in which the pulse weakens or disappears on inspiration.

Constrictive pericarditis is characterised by lack of objective heart signs and by the presence of the features of *venous stasis*. The clinical picture is typical and has come to be known as *Pick's syndrome*. The outstanding signs are: (1) *Ascites*, which is copious and which recurs constantly after paracentesis; (2) *hydrothorax*, which is less commonly present; (3) *enlargement of the liver* from passive congestion (Pick's pseudocirrhosis); (4) *œdema* and *cyanosis* of the face and chest wall; and (5) *raised venous pressure* to as much as three or four times the normal, with *prominent jugular* and other veins.

Marked hydrothorax strongly suggests compression of the left

auricle, while ascites and liver enlargement point to constriction of the right heart.

In spite of the characteristic nature of these symptoms and signs, the *diagnosis* is far from simple, and the best clinicians may be deceived. One difficulty is that cases rarely conform to one or other type of chronic pericarditis, but often present confusing and various combinations of the two. Another difficulty is that the absence of parietal signs does not exclude anterior mediastinal adhesions, since it may mean that the myocardium is becoming exhausted. Furthermore, none of the symptoms of Pick's syndrome is pathognomonic of pericarditis, as they may be produced by other causes of cardiac embarrassment. Electrocardiography, although useful in prognosis, does not assist diagnosis.

It is, in fact, the difficulties in diagnosis which constitute the chief stumbling block to the surgical treatment of chronic pericarditis. Fortunately, expert *radiography* is proving of real assistance, and promises to provide us with a reliable means of diagnosis. The outstanding *X-ray signs* of adhesive pericarditis may be summarised as follows: (1) enlargement of the heart shadow in all directions, (2) fixation of the heart in all positions, and (3) loss of normal cardiac movement with respiration. These three signs are seen in both types of adhesive pericarditis. In constrictive pericarditis the following may also occur: (4) loss of the anterior mediastinal space, and (5) complete immobility of the right border of the heart, while its left border may retain some movement. In adhesions of the apical region to the diaphragm two additional signs may be present: (6) pulling up of the diaphragm at systole, and (7) elongation of the heart shadow on inspiration.

SURGICAL TREATMENT

Adhesive pericarditis is a progressive and inevitably fatal disease. It attacks patients in their youth, completely incapacitates them, and kills them usually in a few years. The actual duration of life is determined by the nature of the infection (tubercle having the worst prognosis), by the degree of cardiac fixation and constriction, and by the condition of the myocardium and cardiac valves.

The failure of medical treatment to do more than palliate the symptoms justifies surgical intervention in every case in which diagnosis is established and the patient has a reasonable chance of surviving operation. Experience has shown that there are two kinds of operative procedure which may be expected to rectify or relieve the mechanical obstacles that encompass the heart: (1) *direct* surgical attack on the

pericardium and its adhesions, and (2) *indirect* procedures which ease the heart's work by removing portions of the thoracic wall or by paralysing the diaphragm.

Operation on the parietes was first proposed by a physician, Brauer (1901), who conceived the brilliant idea of removing a part of the anterior thoracic wall, with the object of releasing the heart. Petersen first performed this operation in 1902, and its simplicity and ease rapidly made it an established procedure. Quite soon, however, it became obvious that whilst very successful in some cases it proved a complete failure in others. Until the reason for these failures was understood, they naturally impeded the further progress of pericardial surgery; but we now know that it is only in the absence of constrictive pericarditis, and when the main cause of cardiac embarrassment is fixation of the heart to the chest wall, that this operation of *precordial costo-chondrectomy* is likely to prove really successful.

Paralysis of the left diaphragm, by alcohol injection or avulsion of the phrenic nerve, was introduced by Sauerbruch in 1925, but is only effective in the rare cases of adhesion between the heart and the diaphragm. It is fortunate that this condition is diagnosable by radiography (see page 3965).

Operation on the pericardium was first suggested by another physician, Weill, as long ago as 1895, but the first actual attempt was made by Hallopeau in 1910. In its early form, the operation was performed with the object of breaking down fibrinous adhesions in the sub-acute stage of pericarditis, but this was illogical as the adhesions were almost bound to re-form. Later, this procedure was applied to chronic cases, single or limited organised adhesions being divided after a deliberate exposure and incision of the pericardium. The operation came to be known as *cardiolysis*, and in the right cases produces brilliant results, but its indications are extremely rare, as the adhesive process is usually too extensive to permit of its application.

Faced with these failures, surgeons abandoned direct operations on the pericardium, until in 1920 Rehn of Frankfort introduced *partial resection* of the parietal pericardium. This was done after freeing as many intrapericardial adhesions as possible, and to prevent their recurrence a fat graft was inserted between the heart and fibrous pericardium. Although this operation proved transitory, it led in due course to the modern operation of *complete pericardiectomy*, for constrictive pericarditis, in which the heart is decorticated to the extent of baring the heart muscle. This brave procedure, although admittedly dangerous, has given a reasonable hope of lasting improvement in the

hitherto hopeless cases of callous pericardial fibrosis. Although it was first performed by Schmieden, and has been warmly advocated by Beck, Griswold and Churchill in America, and by Lenormant and Leriche in France, the credit for its inception must again be given to a physician, Volhard.

OPERATIVE TECHNIQUE

1. *Precordial Costo-chondrectomy* (Brauer's operation). The ideal anæsthesia is bilateral intercostal nerve block with local infiltration, but in children this will need to be supplemented with light general anæsthesia. A flap is raised to the left of the sternum, and the 3rd, 4th, 5th and 6th costal cartilages and ribs are resected for about four inches. Subperiosteal removal of the ribs and cartilages is a safe and rapid procedure, but there is danger of regeneration of the ribs, especially in children. Extraperiosteal resection avoids this danger, but it is a more difficult operation and is associated with the risk of injuring the pleura.

2. *Pericardiectomy* (Volhard-Schmieden). One should always start by doing a precordial costo-chondrectomy, as this not only gives access to the pericardium, but also frees the heart from the rigid parietes. For this reason we do not recommend the trans-sternal approach, in spite of the excellent exposure it provides. The costo-chondrectomy is, of course, extraperiosteal, but owing to the massive fibrosis there is little danger of opening the pleura, provided sufficient care is exercised. The object of the pericardiectomy is to free the heart from its constrictive armour by a maximal degree of decortication ; success depends on a wide exposure of the brown, muscular surface of the heart. The procedure is extremely formidable, as there is no natural line of cleavage between the heart muscle and the fibrous mass covering it, and there is a real danger of tearing through into one of the cavities of the heart, especially when dealing with the right ventricle. Some authorities, in fact, recommend that the right ventricle should be left alone unless skiagrams show that the right border of the cardiac shadow is rigid. The danger of decorticating the auricles is too great to justify the attempt.

The decortication starts with an incision through the whole thickness of the callous mass over the left ventricle ; this is made cautiously and in stages, until the brown muscle-fibres are seen. The mass is then peeled off, partly with the fingers, and partly with the scalpel and scissors ; the fibrous covering usually comes off in layers, and very carefully an increasing area of heart muscle is exposed. When it is necessary to decorticate the right ventricle, additional exposure is provided by removing the edges of the sternum, and by excising the costal cartilages

on the right side. This is the bilateral exposure recommended by Beck, and shown in figure 2179. As soon as the fibrous covering is removed sufficiently, the heart recovers its red colour, and may literally jump in its new-found freedom. Rarely, this liberation is followed by acute dilatation of the right ventricle; Schmieden saw one of his patients die on the table from this cause.

Owing to the dangers of decortication, it would be quite reasonable and prudent to content oneself with a precordial costo-chondrectomy in the first instance, and to perform pericardiectomy as a *second-stage* operation if the relief provided by the first is insufficient.

RESULTS

The following valuable statistics are quoted from Lenormant and Leriche, who were able to collect 181 cases of adhesive pericarditis treated by operation. The figures speak for themselves.

1. *Precordial costo-chondrectomy*: 112 cases, with 6 operation deaths (5·3 per cent). Of 65 followed-up cases, 36 died within five years, mostly from rheumatic cardiopathy or tubercle. The remaining 29 show improvement (1 to 8 years after operation), but only about one half of them could be called cures (about 10 per cent of the total).

2. *Cardiolysis* (for partial adhesions): 2 chronic cases—both cured, and 4 sub-acute cases—1 died, 1 cured, 2 untraced.

3. *Phrenicotomy* (for phreno-pericardial adhesion): 4 cases, all cured.

4. *Partial pericardiectomy* (Rehn's operation): 12 cases, with 2 immediate and 4 early deaths, and only 2 certain survivals after a year.

5. *Total pericardiectomy* (for constrictive pericarditis): 47 cases, with 12 operation deaths (mortality of 25·5 per cent), 4 from wounding heart. In 7 cases the operation was not completed, owing to fibrillation, injury of the heart, etc. Of 32 followed-up cases, 8 died within a year (4 from tuberculosis), while the remaining 24 survived (1 to 6 years after operation). Of the survivals, 2 proved failures, while 22 (nearly half the total) were definitely improved.

PRECORDIAL COSTO-CHONDRECTOMY FOR NON-PERICARDIAL CARDIOPATHIES

The success attending the effort to relieve the cardiac effects of adherent pericardium by resecting the precordial parietes naturally led to the application of the same procedure to other cardiopathies, and particularly to those in which there is a marked disproportion between the size of the heart and the size of the thorax. Under these circumstances the operation virtually constitutes a cardiac decompression.

Enormous *cardiac hypertrophy* is the main indication; but the results have not been brilliant, partly owing to the progressively downward course of rheumatic carditis, but also because few physicians will permit surgical intervention until it becomes obvious that medical treatment will no longer delay the inevitable end. Although mainly performed for rheumatic hypertrophy (usually with valvular disease), the operation has also been attempted for pure hypertrophy and for the cardiac enlargement of arterial or renal disease. It has also been tried a few times for the cardiac complications of extreme *thoracic deformity*, e.g. Pott's disease, scoliosis, and severe sternal depressions. Shipley performed the same operation to relieve the pressure of an *expanding aneurysm* of the aortic arch, while Vaquez suggests that it would be a logical method of freeing the heart, when this is compressed by extensive *pleural* or *pulmonary fibrosis*.

The *technique* of the operation has already been described (see page 3965), but it must be insisted that only regional and local anæsthesia is permissible; several deaths have been attributable to general anæsthesia. Owing to the real danger of injuring the pleura or pericardium (more than one death has been due to empyema), the removal of the ribs and cartilages should always be subperiosteal.

The *results* have been summarised by Lenormant, who reported 7 personal cases and analysed 23 cases in all. Of these, 5 died from the anæsthetic or from pleurisy (operation mortality of 22 per cent). Of the 18 survivals, 7 died by the end of the first year, making a 53 per cent mortality within 12 months. The remaining cases show some improvement, while 4 of them were well and at work 2, 3, 7, and 16 years after the operation.

Even this small proportion of cures strongly suggests that with the establishment of clearer indications for surgical treatment, and with better material in the form of patients a little less near the moribund stage, the results of operative *decompression of the heart* will justify its wider application.

Surgery of Valvular Lesions of the Heart

Although the first suggestion that surgery might play a part in the treatment of valvular disease was made by Lauder Brunton as early as 1902, it was not until after the Great War that surgeons seriously turned their attention to this matter. An enormous amount of experimental work was done on animals, and some twelve operations were undertaken on human patients, ten for mitral stenosis, one for aortic

stenosis, and one for alleged pulmonary stenosis. The interest created by this determined surgical attack proved enormous, and, in fact, to many the term " cardiac surgery " came to mean little more than the operative treatment of valvular lesions. In actual fact, however, all this interest and energy ended in complete failure, so far as the results of surgical intervention are concerned, and we have now come to regard such intervention as futile and ill-advised. Indeed, looking into the future, it would be near the truth to state that valvular lesions will probably constitute almost the only cardiopathy in which surgical treatment is contra-indicated.

Despite the fleeting vogue of valvular heart surgery, the experimental and human work done taught us certain lessons, which have proved of value in the surgical treatment of other cardiac lesions. It is, therefore, quite appropriate to review briefly what has been attempted and what has been accomplished.

The experimental research appears to have started with Tuffier and Carrel's attempts at an open approach to the heart valves, with a temporary interruption of the circulation; this was a laboratory feat which could never have the remotest chance of clinical application. Attempts were then made to reach the valves by puncture of the auricular or ventricular wall, and these proved successful in large series of experiments. Cutler and Beck, Allen and Graham, of America, and Wilson in this country, attacked the problems of valve surgery with great enthusiasm, and perfected the technique of approaching the cardiac valves and operating upon them with a minimum of danger to life. Practically all the work was done on the mitral orifice.

The simplest experimental procedure was a blind attempt to divide the mitral valve with a tenotome, introduced through the wall of the left ventricle. This gave a high mortality, a high incidence of failure to find the valve, and often an insignificant breach when the orifice was reached. The ventricular approach was gradually given up, as it was liable to injure the conducting bundle of His, and an approach through the left auricle became fashionable. To obtain a larger breach of the valve Cutler devised a valvulotome, while Allen and Graham invented a cardioscope by which the section could be performed under direct vision. Wilson then combined the valvulotome and cardioscope into one instrument, which he introduced through the left auricular appendix. By these means the mitral valve was divided in a large number of dogs with a very low mortality (Allen operated on 186 dogs with only two operation deaths and without once missing the valve).

Wilson even went to the extent of producing an experimental mitral stenosis on dogs by inserting strips of pericardium across the mitral orifice, and then proceeded to attempt to undo the stenosis by valvulotomy! He reports in the *British Journal of Surgery* (1930) that although normal animals stand valvulotomy well, dogs with experimental stenosis usually succumb owing to the abrupt change over to mitral incompetence.

It is indeed this abrupt change from a mitral stenosis, which the heart has become accustomed to, and for which compensatory mechanisms have been provided, to a mitral incompetence, for which no protective adaptation can exist, that is mainly responsible for the complete failure of operative treatment on human patients. Up to 1929 ten operations were performed for mitral stenosis, seven by Cutler and Beck, and one each by Allen and Graham, Pribram, and Souttar. Souttar dilated the mitral orifice with a finger introduced through the left auricle; his patient survived, but it seems doubtful if serious stenosis was present. Cutler and Beck's first case, in which the valve was divided with a tenotome, also lived for 4½ years, but at death marked stenosis was again present and the left auricle was very dilated. The other eight cases died at operation or within a week, although both valvulotomes and cardioscopes were employed in some of them.

Apart from the mitral valve, only two attempts appear to have been made at valvular operations. Doyen diagnosed a pulmonary stenosis and divided the pulmonary valve with a tenotome introduced through the right ventricle. The patient died soon after, and the lesion proved to be a serious congenital malformation quite unsuitable for surgery. Tuffier (1924) attacked an aortic stenosis by exposing the ascending aorta and invaginating its wall with his little finger, which he states he pushed into the aortic orifice; the fact that this patient was alive eight years later suggests that his aortic stenosis cannot have been severe.

This melancholy recital of absolute failures, with occasional dubious and partial successes, is an eloquent proof that surgeons were ill-advised to interfere with valvular heart lesions. This unwise intervention arose from the hypothesis that mitral regurgitation is a less dangerous lesion than mitral stenosis. If the transition from stenosis to incompetence could be made gradual enough to give the heart and circulation time to accommodate themselves to the altered conditions, there might be some justification for surgery; but the abrupt change from one to the other is bound to be dangerous, and is almost certainly responsible for the fatal outcome of operation in proved cases of mitral stenosis. Even the

protagonists of valve surgery now admit that the sudden change from stenosis to incompetence is likely to prove fatal, but it seems a pity that this procedure was not more thoroughly investigated experimentally *before* it was tried on human subjects. It is true that Wilson did undertake such an investigation and that he showed that it was not the valvulotomy itself, but the sudden change over from stenosis to incompetence, which was dangerous; but his paper was not published until 1930, and this was *after* the short era of human valvulotomy was ended.

SURGERY OF CORONARY CARDIOPATHIES
(Angina Pectoris, Coronary Arteritis and Thrombosis, etc.)

INTRODUCTION

Although Franck in 1899 suggested that surgical treatment might be applied to the relief of angina pectoris, it is strange that no actual attempt to do this was made before 1916, when Jonnesco performed his first cervical sympathectomy for this purpose. The terrible suffering of the victims of coronary disease, the dread of death that it engenders, the frequency with which this dread is justified by subsequent developments, and the helplessness of medical treatment to give adequate relief, should have proved sufficient incentives for the intervention of surgeons, however great the danger incurred, and however difficult the problems involved. That successful surgical treatment is of such recent development cannot, however, be attributed to the absence of surgical initiative; the chief explanation lies in the lack, until quite modern times, of an accurate understanding of the nerves and blood supply of the heart. In fact, our present knowledge of the anatomy and physiology of cardiac innervation, and of the coronary circulation, has been largely obtained through surgical research, and from the results of actual operative intervention on the part of bold and resourceful surgeons

It must be admitted that even to this day there are important physiological points of which we are uncertain, especially on the question of the vasomotor control of the coronary vessels. But the last few years have witnessed a most heartening advance in the application of surgical treatment to cardiopathies of coronary origin, and although several problems still remain to be settled, there is at last real hope that surgery may provide a reasonable chance of permanent relief, and even of cure, in these crippling and hitherto quite hopeless conditions.

PATHOLOGY AND COURSE

Our knowledge of the pathology of *peripheral arterial disease* should prove of value in elucidating the more obscure pathology of *coronary occlusion*. A peripheral artery may be completely occluded by injury, obliterative arteritis, or thrombosis, and the result will be total loss of function and local necrosis (gangrene), unless an efficient collateral circulation is available. Partial occlusion of peripheral arteries may be produced by vasospasm, when it is intermittent, or by proliferative or sclerosing arteritis, when it is continuous and progressive. The result of such partial occlusion is an ischæmia, which is either intermittent or relative, i.e. it shows itself when a special demand is made on the blood supply of the part. This *relative ischæmia* manifests itself most strikingly by the symptom known as *claudication*, a characteristic and severe pain felt in the muscles and produced by muscular effort. With increasing arterial occlusion, the claudication occurs more frequently and with less effort.

An important fact, which has only recently become understood, is that *organic occlusive disease* of the peripheral arteries may be preceded by functional occlusion, or *vasospasm*, and that this vasospasm may be a causal factor in the production of organic occlusion.

There can be no reason why the pathology of *coronary disease* should differ materially from that of disease of other arteries. It is true that the coronary arteries supply blood to the most vital organ of the body, but this is, after all, only a muscle. Different degrees of vascular occlusion must, again, produce effects of different intensity, and there is ample evidence—experimental, clinical and pathological—to show what these effects are. Complete obliteration of a main coronary artery causes death from cardiac failure, often with fibrillation. Complete obliteration of a branch may result in fatal fibrillation, or in ischæmic infarction of part of the heart muscle, with subsequent necrosis and fibrous tissue replacement, or merely in a temporary disturbance of the cardiac rhythm; the determining factors are the size of the obliterated vessel and the efficiency of the collateral blood supply. Transient occlusion (vasospasm) or partial obliteration (e.g. sclerosis) tend to produce an *intermittent* or a *relative ischæmia* of the heart muscle; this is comparable to the relative ischæmia of peripheral vascular disease, and manifests itself in attacks of severe cardiac pain (angina), typically occurring during effort, and perhaps also in disorders of the cardiac rhythm.

The tendency of all arterial disease is to be *progressive*. Peripheral

arteries may pass through a period of intermittent vasospasm, and then develop degenerative or proliferative changes in their walls, leading to progressive *obliteration*, which, perhaps, is finally accelerated by thrombosis. Whether gangrene or other complications result, or not, depends on the efficiency or otherwise of the collateral circulation. Similarly, it is possible that coronary disease starts as a pure vasospasm, and it may be that the so-called true or functional type of *angina pectoris* represents this early or vasospastic stage of the disease. Later, organic changes occur in the arterial walls, and the condition passes on to a *coronary arteritis* or *sclerosis*, while total *occlusion* may be hastened by an attack of *coronary thrombosis*.

The fate of the heart muscle, and incidentally of the patient, will depend on the degree of occlusion, the size of the obliterated vessel or area, and the efficiency of the local collateral anastomosis. Thus the outstanding clinical feature may be attacks of *anginal pain*, associated with less and less effort (a state of claudication); it may lie in the direction of *disturbance of rhythm or rate;* it may be the development of a *cardiac infarct* and scar, which sooner or later yields to produce a cardiac *aneurysm*, or to cause a *spontaneous rupture* of the heart; it may be a less intense but more diffuse *myocardial degeneration* and *fibrosis*, associated with a relative ischæmia and a gradual but progressive failure of the heart: finally, it may be a more or less *sudden cardiac failure*, perhaps after a period of established fibrillation.

The clinical elucidation of these several cardiopathies of coronary origin lies in the province of the physician, and is therefore only of indirect concern to the surgeon. It is also the physician's prerogative to assist the surgeon in the selection of cases, and to a certain extent *to guide him in the choice of the operative procedure likely to prove of* greatest service in any given case. We shall, therefore, at once proceed to consider the objects and available methods of surgical treatment, but before doing so we may perhaps be permitted to express the hope that in the future our medical colleagues will co-operate more closely with us, and will call us to their assistance, both more frequently and also at a stage of the disease when our intervention has a better chance of success.

OBJECTS AND PRINCIPLES OF SURGICAL TREATMENT

Jonnesco published his well-known paper on the surgical treatment of angina pectoris by cervico-dorsal sympathectomy in 1920. Since that date a veritable avalanche of operative procedures has been introduced, supported by hypotheses differing widely and often contradictory. Successes are claimed and failures admitted by all, and the

mass of publications on what has come to be known as *cardiac neurosurgery* has resulted in a state of hopeless confusion, from which one finds great difficulty in extricating the truth. Practically the only factor on which there is general agreement is that surgical attack should be directed to some part of the sympathetic nerve supply of the heart; but since the most recent research leaves us uncertain of the real action of the sympathetic in such an important function as the vasomotor control of the coronary circulation (see page 3940), it is obvious that even this common ground of agreement rests on a shaky foundation.

The first object of surgical intervention was to prevent or relieve the agonising and crippling pain of *angina pectoris*. This was attempted by interrupting the sensory paths along which painful cardiac sensations travel, or by dividing the nervous connections along which vasospastic or pressor impulses reach the heart. Although very worthy in its objects, this treatment was primarily symptomatic, but the claim soon arose that, by abolishing coronary vasospasm, or by improving the coronary circulation in some other way, surgical intervention was indirectly curative, in that it either stopped or slowed down the morbid processes leading to *organic occlusive disease.*

Within the last three years attempts have been made to attack coronary occlusion, and the disabling and usually fatal cardiopathies resulting from it, from an entirely different angle. The first of these attempts was initiated in December 1932, when the operation of *thyroidectomy* was performed for the first time at Boston, U.S.A., with the object of easing the heart's work by lowering the general metabolism, and in the hope that this would influence beneficially the symptoms and course of cardiac disease. In 1933 Blumgart, Levine and Berlin published their paper on the treatment of angina pectoris and congestive heart failure by removal of the normal thyroid gland, while in 1934 Cutler and Schmitker wrote a paper on the same subject. The results of this intelligent if very indirect procedure have in some respects proved astonishing, and at the moment of writing the operation appears to have established itself as a rational and successful treatment in certain selected cases (see page 3979).

Finally, as recently as November 1935, appeared what we have no hesitation in describing as an epoch-making contribution by Claude S. Beck, entitled *The Development of a New Blood Supply to the Heart by Operation.* Coronary occlusion produces its painful and ultimately fatal cardiac ischæmia because the chances of the heart acquiring a collateral circulation by its external anastomoses are negligible (see page 3940). Beck evolved the remarkable conception of

providing the ischæmic heart with an adequate collateral blood supply by a muscle-grafting operation. The operation, and the principles which govern it, will be considered at length a few pages hence, but it should be stated at once that this is the first surgical procedure which actually strikes at the root of coronary cardiopathy, and which gives real hope that the time is near at hand when surgery will be able to do more than merely palliate cardiac symptoms.

OPERATIONS ON THE CARDIAC NERVES

There are three possible ways in which the heart can be influenced by neurosurgical attack: (1) through its vasomotor nerves, (2) through its motor or pressor nerves, and (3) through its sensory nerves. The attempt to influence the *vasomotor* control of the coronary vessels is the most logical of these objects, inasmuch as it aims at elimination of some of the factors responsible for organic coronary disease, as well as the relief of cardiac pain. It has already been stated (see page 3940) that the exact nature of the vasomotor control of the coronary circulation is not yet settled; nevertheless, it appears to be certain that removal of the sympathetic nerve supply to the heart *increases the coronary blood-flow.* The future must decide whether this is due to abolition of vasospastic influences, or to altered conditions of the heart's work. Whatever its cause, the increased flow of blood through the coronary vessels is likely to exert a beneficial effect on the cardiac ischæmia, whether this is intermittent, as in the vasospasm probably responsible for functional angina, or continuous and relative, as in the early stages of coronary arteritis.

Operative interruption of the *motor* or *pressor* sympathetic nerves tends to decrease the motor activity of the heart, in conditions of relative cardiac ischæmia, where it is particularly desirable to prevent the work of the heart from exceeding its limited capacity for muscular effort. Unfortunately, complete motor denervation of the heart is a most formidable procedure, entailing bilateral extirpation of the sympathetic chain, from the superior cervical ganglion down to the fifth thoracic ganglion, and also denervation of the suprarenal medulla (since it has been proved that even small quantities of adrenalin can evoke pressor effects on the denervated heart). Apart from the grave operative risk of such an extensive procedure on a cardiopathic patient, it has the added and serious danger of leaving the heart entirely unable to respond to effort. More limited attacks on the motor sympathetic give little or no benefit, owing to the widespread connections of the motor fibres.

Interruption of the sensory sympathetic paths (see page 3942) is free from these drawbacks, gives the most dependable results, and is rapidly becoming the established method of attack in cardiac neurosurgery. Cardiac sensation can be largely abolished by effective division of the sensory pathway, and angina, and other forms of heart pain, can be cured or relieved, without in any way impairing the heart's efficiency, or its ability to respond to effort.

Sir James Mackenzie objected to the surgical treatment of angina pectoris on the ground that by abolishing pain it would remove an important warning signal against effort beyond the heart's limited capacity. This objection has not proved valid, as in actual practice cardiac sensation is rarely abolished to such an extreme degree, and warning signals of some kind still occur when anything like dangerous effort is indulged in. A striking proof of this is given by White in his admirable monograph on the sympathetic system published in 1935 : *a number of angina cases were treated by complete sensory denervation* on the left side, with the result that anginal pain and all cardiac sensations were abolished to the left of the mid-line, but danger signs in the form of slight right-sided pain and vasomotor phenomena in the face or abdomen still occurred in the presence of effort. As a matter of fact, most failures after neurosurgical treatment for angina have been due to a too limited sensory denervation, and the dangers of too complete an interruption are undoubtedly less serious than some people would have us believe.

Although we have discussed the nerve surgery of the heart on the basis of its three distinct forms of nerve supply, in actual fact it is *impossible to perform a successful neurosurgical operation which* limits itself to the vasomotor, pressor, or sensory innervation only. Any sympathectomy sufficiently extensive to be of service is bound to interrupt all three forms of cardiac innervation, although it is true that they may not be interrupted to an equal degree. The results of surgical intervention depend partly on the proportion in which the three forms of nerve supply are interrupted, and partly on the degree of such interruption. When it is added that the anatomical arrangement of the cardiac nerves and their connections is subject to considerable variation, as is also the anatomical knowledge and surgical skill of operators, it becomes easy to see why the results claimed for the numerous and often dissimilar surgical procedures are so inconsistent and confusing.

An attempt to extract the more successful neurosurgical operations on the heart from the large list of attempted procedures leaves the following small group for further consideration. It should first be noted

that, while the best results of neurosurgery are obtained in cases of early and uncomplicated or functional angina pectoris (angina simplex), in which the outstanding lesion is probably an intermittent coronary vasospasm, some relief and amelioration can be expected even in the presence of early organic coronary disease with relative cardiac ischæmia. These latter cases, however, are far more suitable for the more modern procedures of thyroidectomy and Beck's grafting operation. Surgical treatment must be *carefully avoided* in cases of *hysterical* angina or pseudo-angina.

The following operations are all directed to the cervico-dorsal sympathetic system, and for a description of *operative technique* the reader is referred to the article on the Sympathetic Nervous System in Vol. II, page 3099.

1. *Complete Cervical Sympathectomy.* This is the procedure suggested by Franck, and performed and warmly defended by Jonnesco. The operation may be done on the left or on both sides, and in one stage or two. Its object is to remove the entire cervical sympathetic chain, down to and including the stellate or 1st thoracic ganglion. Before 1926, bilateral complete cervical sympathectomy was the most effective method of cardiac denervation we had; in fact, until about that date it was believed that this procedure interrupted almost all the central connections of the cardiac plexus. We now know that, although it abolishes most of the motor and vasomotor sympathetic fibres, a variable but large proportion of the sensory connections are left untouched. In spite of this it is quite certain that the operation cures or relieves a considerable percentage of cases submitted to it. Its great drawback is a *high mortality*, to which attention was drawn by Danielopolu, and which has stood in the way of the procedure ever becoming really popular. Leriche and Fontaine attribute this mortality to the trauma and shock caused by speedy and rough operative technique, and believe that with more gentle and slower operations the risk could be greatly lowered. We doubt, however, if the danger of such a huge procedure could be anything but great in a patient with a cardiac disorder. The operation is tedious and difficult, particularly in short-necked individuals, and has now been replaced by simpler and safer procedures.

2. *Suprastellate Sympathectomy.* The high mortality of Jonnesco's operation led to the introduction of more conservative procedures. Thus, in 1923, Coffey and Brown claimed to relieve some cases of angina by *resection of the superior cervical ganglion.* This is above the level of sensory connections (see page 3943), and any benefit which results must be attributed to division of motor or vasomotor fibres only. In 1927,

Danielopolu recommended a very conservative operation which amounts to a *post-ganglionic ramisectomy*. Both procedures spare the stellate ganglia and the thoracic connections of the cardiac sympathetic, and completely preserve the efficiency of the heart. But there is no evidence that removal of the stellate ganglia impairs the cardiac efficiency, and the scope of these conservative operations is far too limited, and their results too uncertain, to justify their retention. An exception might perhaps be made in short-necked patients, in whom resection of the upper and middle ganglia may be less difficult and dangerous than stellectomy.

3. *Stellectomy*. The effects of stellectomy can be imitated by infiltration of the stellate ganglia with novocaine. Leriche and Fontaine claim to have performed *novocaine stellate block* a hundred times, and to have obtained instant though temporary arrest of anginal and asthmatic crises. They recommend it in the treatment of *anginal attacks* which resist the usual medical measures. Since it does give a definite chance of relief, and also diminishes the tendency to fibrillation during a severe crisis, it is certainly worthy of trial.

Resection of the left or of both stellate ganglia may at the moment be regarded as the best of the operative sympathectomies for the permanent relief of angina. It is almost as effective as Jonnesco's complete cervical sympathectomy, and it is safer. Leriche and Fontaine report 70 per cent of good results after stellectomy for angina, but with certain other operators the figure is nearer 50 per cent. Its success or failure must largely depend on the anatomical arrangement of the sensory cardiac nerves. When the operation succeeds, it does so because the bulk of the afferent fibres pass through the stellate ganglia, but it is bound to fail when the thoracic cardiac nerves (see page 3943) carry a large proportion of the sensory nerves. Preliminary novocaine block during an anginal attack should assist us in distinguishing between these two types of sensory pathway, and may thus give valuable information of the likelihood and degree of relief which can be expected from a stellectomy.

4. *Alcohol Injection of Upper Thoracic Ganglia and Rami.* The frequent failure to abolish cardiac pain by cervical and stellate sympathectomy led to the anatomical discovery that post-ganglionic fibres reach the cardiac plexus from the upper five thoracic sympathetic ganglia, as well as from all three cervical ganglia, and that sensory impulses reach the cord only by the upper five thoracic white rami. This discovery was soon followed by a transference of surgical attack from the cervical to the thoracic ganglia and rami. *Surgical resection* of the upper thoracic ganglia was tried with absolute

provided the cardiopathy has been definitely ameliorated, very slight bodily activity may be begun, and most gradually and carefully increased. The rest of the treatment consists of careful regulation of bodily activity and thyroid administration; the object is to find and keep an optimum level, in each patient, which will maintain the hypothyroid state, without myxœdema or an unnecessarily vegetative existence, on the one hand, and without threatened return of symptoms or signs of decompensation, on the other.

Results and Indications. The published results of thyroidectomy show that the operation is, on the whole, more successful in selected cases of congestive failure than in cases of angina and coronary occlusion. Of the 75 cases published by Blumgart and his associates, 25 were cases of angina and 50 of congestive failure. Blumgart's angina results show a mortality (post-operative) of 8 per cent, complete relief in 35 per cent, partial relief in 50 per cent, and failure in 15 per cent. The figures of 29 cases of angina published by Cutler and Schnitker are very similar. Blumgart's 50 cases of congestive failure show the following results: operative mortality of 12 per cent (none in the last 22 cases), subsequent mortality (within 10 months) of 13 per cent, marked improvement (return to work) in 55 per cent, partial improvement in 13 per cent, and failure of 7 per cent. Considering that this last group were all cases with actual congestive failure, many of them with considerable decompensation, and all incapacitated from work prior to operation, these figures are, to say the least extremely encouraging.

It is, indeed, in the treatment of *early congestive failure* that we feel the future of total thyroidectomy lies. Angina can be relieved by effective neurosurgery, while coronary occlusion will before long probably find its cure in grafting operations, but the large group of patients with a failing rheumatic heart cannot be benefited by either of these procedures, and the only hope of relieving their distress, prolonging their lives, and perhaps restoring them to a useful degree of activity, at present lies in thyroidectomy.

The operation is by no means free from danger, and Blumgart himself admits that it should be abandoned in favour of paravertebral alcohol injections (or other treatment) in old patients with coronary thrombosis and cardiac pain, in cardiopathies associated with syphilitic aortitis and aortic regurgitation, and in all cases with a low basal metabolic rate. It would probably be wise to add to this list all cases of [illegible] angina, and

Danielopolu recommended a very conservative operation which amounts to a *post-ganglionic ramisectomy.* Both procedures spare the stellate ganglia and the thoracic connections of the cardiac sympathetic, and completely preserve the efficiency of the heart. But there is no evidence that removal of the stellate ganglia impairs the cardiac efficiency, and the scope of these conservative operations is far too limited, and their results too uncertain, to justify their retention. An exception might perhaps be made in short-necked patients, in whom resection of the upper and middle ganglia may be less difficult and dangerous than stellectomy.

3. *Stellectomy.* The effects of stellectomy can be imitated by infiltration of the stellate ganglia with novocaine. Leriche and Fontaine claim to have performed *novocaine stellate block* a hundred times, and to have obtained instant though temporary arrest of anginal and asthmatic crises. They recommend it in the treatment of *anginal attacks* which resist the usual medical measures. Since it does give a definite chance of relief, and also diminishes the tendency to fibrillation during a severe crisis, it is certainly worthy of trial.

Resection of the left or of both stellate ganglia may at the moment be regarded as the best of the operative sympathectomies for the permanent relief of angina. It is almost as effective as Jonnesco's complete cervical sympathectomy, and it is safer. Leriche and Fontaine report 70 per cent of good results after stellectomy for angina, but with certain other operators the figure is nearer 50 per cent. Its success or failure must largely depend on the anatomical arrangement of the sensory cardiac nerves. When the operation succeeds, it does so because the bulk of the afferent fibres pass through the stellate ganglia, but it is bound to fail when the thoracic cardiac nerves (see page 3943) carry a large proportion of the sensory nerves. Preliminary novocaine block during an anginal attack should assist us in distinguishing between these two types of sensory pathway, and may thus give valuable information of the likelihood and degree of relief which can be expected from a stellectomy.

4. *Alcohol Injection of Upper Thoracic Ganglia and Rami.* The frequent failure to abolish cardiac pain by cervical and stellate sympathectomy led to the anatomical discovery that post-ganglionic fibres reach the cardiac plexus from the upper five thoracic sympathetic ganglia, as well as from all three cervical ganglia, and that sensory impulses reach the cord only by the upper five thoracic white rami. This discovery was soon followed by a transference of surgical attack from the cervical to the thoracic ganglia and rami. *Surgical resection* of the upper thoracic ganglia was tried with absolute

that, while the best results of neurosurgery are obtained in cases of early and uncomplicated or functional angina pectoris (angina simplex), in which the outstanding lesion is probably an intermittent coronary vasospasm, some relief and amelioration can be expected even in the presence of early organic coronary disease with relative cardiac ischæmia. These latter cases, however, are far more suitable for the more modern procedures of thyroidectomy and Beck's grafting operation. Surgical treatment must be carefully avoided in cases of *hysterical* angina or pseudo-angina.

The following operations are all directed to the cervico-dorsal sympathetic system, and for a description of *operative technique* the reader is referred to the article on the Sympathetic Nervous System in Vol. II, page 3099.

1. *Complete Cervical Sympathectomy.* This is the procedure suggested by Franck, and performed and warmly defended by Jonnesco. The operation may be done on the left or on both sides, and in one stage or two. Its object is to remove the entire cervical sympathetic chain, down to and including the stellate or 1st thoracic ganglion. Before 1926, bilateral complete cervical sympathectomy was the most effective method of cardiac denervation we had; in fact, until about that date it was believed that this procedure interrupted almost all the central connections of the cardiac plexus. We now know that, although it abolishes most of the motor and vasomotor sympathetic fibres, a variable but large proportion of the sensory connections are left untouched. In spite of this it is quite certain that the operation cures or relieves a considerable percentage of cases submitted to it. Its great drawback is a *high mortality*, to which attention was drawn by Danielo

Danielopolu recommended a very conservative operation which amounts to a *post-ganglionic ramisectomy.* Both procedures spare the stellate ganglia and the thoracic connections of the cardiac sympathetic, and completely preserve the efficiency of the heart. Leriche and Fontaine report 70 per cent of good results after stellectomy for angina, but with certain other operators the figure is nearer 50 per cent. Its success or failure must largely depend on the anatomical arrangement of the sensory cardiac nerves. When the operation succeeds, it does so because the bulk of the afferent fibres pass through the stellate ganglia, but it is bound to fail when the thoracic cardiac nerves (see page 3943) carry a large proportion of the sensory nerves. Preliminary novocaine block during an anginal attack should assist us in distinguishing between these two types of sensory pathway, and may thus give valuable information of the likelihood and degree of relief which can be expected from a stellectomy.

4. *Alcohol Injection of Upper Thoracic Ganglia and Rami.* The frequent failure to abolish cardiac pain by cervical and stellate sympathectomy led to the anatomical discovery that post-ganglionic fibres reach the cardiac plexus from the upper five thoracic sympathetic ganglia, as well as from all three cervical ganglia, and that sensory impulses reach the cord only by the upper five thoracic white rami. This discovery was soon followed by a transference of surgical attack from the cervical to the thoracic ganglia and rami. *Surgical resection* of the upper thoracic ganglia was tried with absolute

success so far as the relief of cardiac pain was concerned, but it proved much too dangerous a procedure for patients with coronary disease.

Following the example of Mandl of Vienna, *paravertebral alcohol injections* into the upper thoracic ganglia and rami began to be given, and soon proved very successful in abolishing cardiac pain, and comparatively free from danger to life. Lists of successful cases were published by several clinics, while recently (1935) the procedure has been extensively tried and warmly advocated by J. C. White of Harvard. He analyses results in 40 patients, all with intense cardiac pain unrelieved by medical measures, many with severe relative ischæmia or even coronary thrombosis, and some with actual congestive failure; his figures show one operative death, nearly 70 per cent cures (90 to 100 per cent relieved), and nearly 20 per cent good improvements (relieved 50 per cent or more). The failures he attributes to imperfect injection and gives convincing evidence in support of this contention.

Were it not for its *technical difficulty*, and for the unpleasant *complications* to which it is liable, paravertebral alcohol injection would by now have replaced every other form of sympathetic neurosurgery. Unfortunately, accurate injection at a depth of two to three inches, of structures so small and so hidden as the sympathetic ganglia and white rami, is bound to be technically very difficult, and requires long and careful study and practice. Of the *complications*, apart from the failures, the most common is an *intercostal neuritis*. The alcohol injection permanently destroys the sympathetic rami, but only temporarily anæsthetises the thicker and more strongly sheathed intercostal nerves; after two or three weeks' anæsthesia the intercostal nerves pass on to an irritative neuritis, which may be slight and short-lived, but is sometimes severe and prolonged. Among less common complications are *pneumothorax*, due to pricking of the lung, and *pleuritic pain*, caused by scratching of the pleura.

Because of the technical difficulty of a successful injection, and the liability to troublesome intercostal neuritis, we feel that the alcohol treatment should be reserved for cases of severe anginal pain which, because of coronary disease or threatening failure, are poor operative risks for stellectomy, thyroidectomy or grafting operations. It is hardly necessary to add that it should be employed only by surgeons who thoroughly understand the technique of its administration. For a full description of this technique the reader is referred to the excellent monograph by J. C. White on the *Autonomic Nervous System* (1935) to which we have already alluded. A brief account will be found in Vol. II, page 3198.

OPERATIONS FOR DISORDERS OF CARDIAC RHYTHM

Essential or paroxysmal tachycardia is a distressing disturbance of the pace-making mechanism of the heart, and is usually controlled by medical treatment. Occasionally, medical treatment fails to stop or abort the attacks, which may become so severe as to bring on congestive failure of the heart. Stellectomy has been suggested for such cases by Leriche and Fontaine, who claim one cure $7\frac{1}{2}$ years after operation. On the other hand, J. C. White investigated two cases by injecting novocaine into the upper thoracic ganglia, in one of which the heart rate was brought down from 210 to 83 for three weeks ; he believes, however, that in children, at least, ganglionectomy should be preferred to alcohol injections.

Leriche and Fontaine go so far as to suggest that sympathectomy may be tried in Stokes Adams' *bradycardia,* in the belief that by improving the coronary blood flow we might influence the conducting system of His. Assuming, however, that bradycardia is a manifestation of coronary deficiency, it is more likely to be influenced by operations more definitely directed to the blood supply of the heart.

THYROIDECTOMY IN TREATMENT OF CARDIOPATHIES

Although only three years have elapsed since the normal thyroid was first extirpated for heart disease, the operation is now firmly established as a measure of real therapeutic value. Even in this short period it has been possible to form an opinion of the usefulness of the operation, of its indications, and of its results. The pioneer work of Blumgart, Levine and Berlin has already been referred to (see page 3973), and in the last two years further publications by them, Cutler, and others, have done much to bring this valuable procedure to the notice of the surgical world.

It has been known for many years that the removal of a toxic thyroid may benefit materially any associated cardiac lesion, but the extirpation of the normal thyroid is done for a different reason, viz., to ease the work of the heart by lowering the general metabolism. When first tried for this purpose the thyroidectomy was sub-total, but this soon proved of little or no service. Total thyroidectomy, however, produced very striking relief in both angina pectoris and early congestive failure of the heart. The actual results differ materially in these two cardiopathies, as might indeed be expected from their quite dissimilar pathology ; but, in general, cardiac pain and distress in the first, or the congestive phenomena of decompensation in the second, may be

expected to diminish or disappear when the basal metabolic rate falls *to minus 20 or 25.* Usually it takes from three to four weeks for this fall to be fully established. The maintenance of this low level of metabolism will not be disturbed by the minute doses of thyroid extract which have to be taken to avoid myxœdema.

The experience of the last three years has shown that thyroidectomy must not be regarded as a panacea for all sufferers from serious heart disease. The attempt to accept and apply the operation in any such sense can only ultimately discredit a procedure which, within proper limits, is capable of conferring very real and lasting benefit. In a recent publication Mixter, Blumgart and Berlin emphasise three points, observation of which is essential to success: (1) pre-operative study and careful selection of cases, (2) special operative technique and post-operative care, and (3) accurate interpretation of the results, comparison of what is expected with what is gained, and derivation of the indications and contra-indications for the operation from the knowledge thus obtained. *It is under these headings that we shall endeavour to present* an outline of this important procedure.

Pre-operative study and selection. Surgery should never be employed as an agent of euthanasia, and no case should be submitted to operation owing to the failure of medical treatment, unless there is a reasonable chance of recovery. The somewhat high immediate mortality which first attended the operation led to a more careful pre-operative study of cardiopathic patients, and a closer co-operation between the physicians and surgeons in charge, with the result that careful *selection of cases* was soon found to be the most important factor in success. It is now known that cases of advanced congestive heart failure, in which decompensation exists to the degree of serious pulmonary congestion, and which fail to respond to a period of complete rest and medical treatment, will not improve after thyroidectomy, and are likely to die from it. We also know that patients with a low basal metabolic rate (minus 10 or less) are unlikely to derive any benefit from it, and that cases of coronary thrombosis make bad operation risks. It has further become obvious that although thyroidectomy may considerably relieve the distressing symptoms of angina and other coronary cardiopathies, its best results are obtained in early congestive failure.

Another factor of great importance is the *anæsthesia.* Many of the early operative deaths occurred under general anæsthesia, and there can be no question whatever that the operation should only be performed with local novocaine infiltration. The strongest possible [illegible]ort of this is given by Mixter, Blumgart and Berlin, who repor[illegible] their last

22 cases of congestive failure were operated on under local anæsthesia without a single operative fatality. The same authorities advise against the administration of more than a minimal quantity of sedative drugs, both before and after the operation, on the ground that thereby the cough reflex is not abolished, and the patient is protected against the very real danger of post-operative pneumonia.

Operative technique. The median approach, by dividing the isthmus and removing the two lobes separately, has been abandoned as too dangerous, and the usual thyroidectomy approach is employed. After infiltrating the tissues in front and to each side of the gland, a long collar incision is made a full inch above the sternum, down to the infra-hyoid muscles. These are split from the larynx to the sternum and widely separated. The previous novocaine infiltration will now prove helpful by separating the tissue planes, and facilitating the isolation and removal of the gland. Care must be taken not to infiltrate the tracheo-œsophageal groove, as this may cause recurrent laryngeal paralysis; serious results may occur if both nerves are blocked. The superior thyroid vessels are now divided and the upper poles of the gland mobilised; the other vessels are then tied and cut as near as possible, to the gland which is gently enucleated from its surroundings. By keeping very close to the gland the dangers of injuring the recurrent laryngeal nerve, and of removing the parathyroids, are considerably diminished. Blumgart and his associates do not regard these dangers very seriously, although they admit that mild tetany may occur, and that paralysis of one vocal cord from injury of the recurrent is a reason for stopping the operation at a hemi-thyroidectomy. But Cutler and Schnitker appear to consider these accidents as quite likely, and insist that the recurrent laryngeal should be actually seen at the operation, to safeguard it against injury, and that very special care should be exercised to avoid removal of the parathyroids.

The post-operative care of the patient should be shared between the physician and the surgeon. The most strict supervision, bodily rest, and medical treatment must be continued until anginal symptoms have cleared up, or until there is evidence of good cardiac compensation. In congestive failure the operation lowers the demand made upon the heart, and by comparison raises the supply of cardiac activity; thus a state of decompensation gives place to one of compensation. The success or failure of the operation will not be apparent until the basal metabolic rate has been reduced to the necessary level to give real relief to cardiac effort, i.e. about minus 20, and this does not usually occur until the third or fourth week. When this stage is reached, and

provided the cardiopathy has been definitely ameliorated, very slight bodily activity may be begun, and most gradually and carefully increased. The rest of the treatment consists of careful regulation of bodily activity and thyroid administration; the object is to find and keep an optimum level, in each patient, which will maintain the hypothyroid state, without myxœdema or an unnecessarily vegetative existence, on the one hand, and without threatened return of symptoms or signs of decompensation, on the other.

Results and Indications. The published results of thyroidectomy show that the operation is, on the whole, more successful in selected cases of congestive failure than in cases of angina and coronary occlusion. Of the 75 cases published by Blumgart and his associates, 25 were cases of angina and 50 of congestive failure. Blumgart's angina results show a mortality (post-operative) of 8 per cent, complete relief in 35 per cent, partial relief in 50 per cent, and failure in 15 per cent. The figures of 29 cases of angina published by Cutler and Schnitker are very similar. *Blumgart's 50 cases of congestive failure show the* following results: operative mortality of 12 per cent (none in the last 22 cases), subsequent mortality (within 10 months) of 13 per cent, marked improvement (return to work) in 55 per cent, partial improvement in 13 per cent, and failure of 7 per cent. Considering that this last group were all cases with actual congestive failure, many of them with considerable decompensation, and all incapacitated from work prior to operation, these figures are, to say the least, extremely encouraging.

It is, indeed, in the treatment of *early congestive failure* that we feel the future of total thyroidectomy lies. Angina can be relieved by effective neurosurgery, while coronary occlusion will before long probably find its cure in grafting operations; but the large group of patients with a failing rheumatic heart cannot be benefited by either of these procedures, and the only hope of relieving their distress, prolonging their lives, and perhaps restoring them to a useful degree of activity, at present lies in thyroidectomy.

The operation is by no means free from danger, and Blumgart himself admits that it should be abandoned in favour of paravertebral alcohol injections (or other treatment) in old patients with coronary thrombosis and cardiac pain, in cardiopathies associated with syphilitic aortitis and aortic regurgitation, and in all cases with a low basal metabolic rate. It would probably be wise to add to this list all cases of severe angina, and those of arteriosclerotic and hypertensive heart disease, and to reserve thyroidectomy particularly for patients with early *congestive failure and without severe cardiac pain.*

REVASCULARISATION OF THE HEART BY OPERATION

The great frequency of occlusive disease of the coronary arteries, its painful and distressing manifestations, and its inevitably fatal termination, often appallingly sudden, makes it the most dreaded of cardiac disorders. It attacks people in the prime of life, and shows a special predilection for men of intelligence and industry, and for experienced professional, commercial and social workers, when they can least be spared. Medical treatment cannot do more than alleviate some of the distressing symptoms and perhaps postpone for a while the inevitable end, but at times it fails even to do this much. Neurosurgical operations and total thyroidectomy often give more marked and more permanent relief, and they may delay the fatal termination for a longer period; but in the nature of things they can never be really curative, since they cannot completely arrest the organic processes which deprive the heart muscle of the blood supply necessary to the maintenance of its function.

Sooner or later surgical art was bound to attack the problem of coronary occlusion at its root, by providing a new blood supply to the ischæmic heart muscle, and the name of Claude Beck will go down to posterity as that of the man who made the first successful attempt to do this on a human subject. Whether his operation will stand the test of time, or whether it becomes in due course replaced by other and simpler or more satisfactory procedures, the first great step has been taken, and the tenacity and initiative of surgeons may be trusted to improve and widen its principles and scope, until this surgical achievement becomes equal to the tremendous need for it.

The heart is defenceless against the interruption of its normal blood supply, because the serous sac which encloses it deprives it of the chance of acquiring an adequate external collateral supply. The only continuity between the coronary circulation and extracardiac structures is provided by the scanty fat and other avascular tissues on the walls of the great vessels. In extremely exceptional cases even this poor scaffold for an extracardiac anastomosis is capable of development, as is shown by the survival of a few cases with complete occlusion of one or even both coronary arteries, but the occlusion has to occur so very slowly that it is not surprising to discover that such cases are absolute rarities. In the vast majority, death occurs long before any external anastomosis even begins to function.

Bringing the surface of the ischæmic heart into direct contact with an extracardiac vascular bed is the obvious solution of this problem.

both procedures are in the stage of trial, and that only future experience will decide whether one or the other, or perhaps some method as yet undiscovered, will ultimately prove the best.

Beck's Muscle-grafting Operation. Beck's first attempt to revascularise the human heart was a complete success. The operation was performed in February 1935, on a man of 48 with severe anginal attacks, moderate hypertension and arteriosclerosis, and a generally typical picture of coronary sclerosis. Under gas and oxygen anæsthesia the insertion of the left pectoralis major was mobilised, and a curved incision made to the left of the sternum. A pedicled flap was cut from the lower part of the pectoral muscle (fig. 2184), while the upper part of the pectoral was incised a little lateral to the sternum and lifted from the 3rd, 4th and 5th cartilages. These cartilages were then removed, and the intercostal muscles divided laterally, preserving their internal mammary supply. The pericardium was opened from apex to base (fig. 2185), and its serous lining, as well as the epicardium, removed in shreds with a burr. This caused extra systoles and some cardiac dilatation, which necessitated rest periods. The pedicled graft was then split, and both parts wrapped round the heart, and sutured laterally and posteriorly to the parietal pericardium (fig. 2186). The intercostal muscle bundles, carrying the internal mammary artery, and the inner margin of the pectoral muscle were brought beneath the sternum and also attached to the pericardium. Finally, the lateral margin of the pectoral was turned in so that its cut surface touched the heart (fig. 2187), and the pectoral fascia and skin wound were sutured without drainage.

Seven months after the operation the patient claims that he is cured. He has had no precordial pain or distress, and is able to work as a gardener. In an addendum to his article Beck reports six additional operations, making seven in all. His second patient died after a week from thrombosis of the bifurcation of the aorta. The third had had a total thyroidectomy performed 18 months previously and was practically bedridden; at operation the sclerosed and tortuous coronary arteries could be palpated; in less than 3 months he was able to take double the amount of thyroid, to bring up his B.M.R. from minus 20 to plus 2 without any pain, and to spend 6 to 8 hours out of bed daily. The other patients survived the operation, but a sufficiently long interval had not elapsed to comment on them.

tendon of the diaphragm, pulled the omentum into the pericardial cavity, destroyed the epicardium with iodine, and wrapped the omentum round the heart, fixing it *in situ* with two sutures. Three to *six weeks later he ligatured the left coronary at its origin. All the dogs* survived and showed no disturbance of cardiac function, while control animals without the *omentocardiopexy* invariably succumbed. At a subsequent operation extensive adhesions were found between the omentum and heart, which bled profusely when slightly separated. It should be observed that Rienhoff used old dogs for his experiments, and it may be this, rather than the different vascular bed employed, which explains the greater protection he obtained against one-stage occlusion of a main coronary trunk.

In January 1936 O'Shaughnessy published in the *British Journal of Surgery* a series of experimental omentocardiopexies on cats and dogs, with very similar results. He showed that injection material reached the myocardium from the omentum. It is interesting to note that one of his animals died from a strangulated hernia of the intestine, which had passed into the thorax through the diaphragmatic *opening.*

Beck's, Rienhoff's and O'Shaughnessy's experiments prove quite conclusively that the ischæmic heart can acquire a collateral circulation, provided it is brought into contact with a vascular bed, and that this may prove adequate to meet the heart's needs. An obvious question which arises is whether or not the adhesions between the heart, on the one hand, and the pericardium, skeletal muscle or omentum, on the other, are likely to hamper cardiac movements and function. In the section on adhesive pericarditis it was pointed out that only two types of adhesive process interfere with the heart, viz. fixation to rigid structures, and constrictive adhesions. In the procedures we are now considering neither of these conditions applies, and there is no reason to expect any appreciable cardiac embarrassment.

In the application of these procedures to the human subject two further questions arise. In Beck's operation of muscle-grafting the nerve supply to the pedicled graft is partly destroyed, and this may lead to atrophy and diminished vascularity of one source for the collateral cardiac blood supply; Beck himself, however, does not consider this objection to be valid. The employment of omental grafts (omento-cardiopexy) is free from any such objection, but it involves the creation of an opening in the diaphragm, which may be a cause of subsequent diaphragmatic hernia, or which may by fibrous contraction ultimately lead to strangulation of the omental graft. It must be stressed that

both procedures are in the stage of trial, and that only future experience will decide whether one or the other, or perhaps some method as yet undiscovered, will ultimately prove the best.

Beck's Muscle-grafting Operation. Beck's first attempt to revascularise the human heart was a complete success. The operation was performed in February 1935, on a man of 48 with severe anginal attacks, moderate hypertension and arteriosclerosis, and a generally typical picture of coronary sclerosis. Under gas and oxygen anæsthesia the insertion of the left pectoralis major was mobilised, and a curved incision made to the left of the sternum. A pedicled flap was cut from the lower part of the pectoral muscle (fig. 2184), while the upper part of the pectoral was incised a little lateral to the sternum and lifted from the 3rd, 4th and 5th cartilages. These cartilages were then removed, and the intercostal muscles divided laterally, preserving their internal mammary supply. The pericardium was opened from apex to base (fig. 2185), and its serous lining, as well as the epicardium, removed in shreds with a burr. This caused extra systoles and some cardiac dilatation, which necessitated rest periods. The pedicled graft was then split, and both parts wrapped round the heart, and sutured laterally and posteriorly to the parietal pericardium (fig. 2186). The intercostal muscle bundles, carrying the internal mammary artery, and the inner margin of the pectoral muscle were brought beneath the sternum and also attached to the pericardium. Finally, the lateral margin of the pectoral was turned in so that its cut surface touched the heart (fig. 2187), and the pectoral fascia and skin wound were sutured without drainage.

Seven months after the operation the patient claims that he is cured. He has had no precordial pain or distress, and is able to work as a gardener. In an addendum to his article Beck reports six additional operations, making seven in all. His second patient died after a week from thrombosis of the bifurcation of the aorta. The third had had a total thyroidectomy performed 18 months previously and was practically bedridden; at operation the sclerosed and tortuous coronary arteries could be palpated; in less than 3 months he was able to take double the amount of thyroid, to bring up his B.M.R. from minus 20 to plus 2, without any pain, and to spend 6 to 8 hours out of bed daily. The other patients survived the operation, but a sufficiently long interval had not elapsed to comment on them.

Tumours of the Heart

Considerably over a hundred cases of tumours and cysts of the heart are on record. The *tumours* are mostly secondary carcinomata, fibromata and rhabdomyomata. Morbid effects may be produced by pressure on the coronary, pulmonary, or other vessels entering and leaving the heart, by interference with the conducting mechanism or the valves, by encroachment on the heart chambers, and by destruction of the myocardium. There is, unfortunately, no recognisable clinical picture, and diagnosis has so far proved practically impossible. *Hydatid cysts* have also affected the heart; diagnosis has not yet been accomplished, but the complication might be suspected in a case of generalised pulmonary hydatid disease with syncopal attacks.

Two instances of surgical intervention are mentioned by Lenormant and Leriche. In one, Leriche himself discovered a sarcoma of the right auricle, while in the other, Lopez found a hydatid of the heart during a search for an alleged mediastinal tumour. Both cases died after an attempt at partial removal of the tumour.

Surgical Treatment of Cardiac Arrest

Nearly all cases of suspended animation which can be treated surgically occur on the operating table and under general anæsthesia. Usually the cardiac arrest is attributable to the anæsthetic, but it is not chloroform which is always responsible. The writer has seen it occur twice with open ether and twice with a short gas administration, all four cases proving fatal. One cannot help expressing the conviction that some cases of total cardiac arrest are directly due to preventable error in anæsthetic technique, and more particularly to inattention on the part of the anæsthetist, and to his failure to inform the surgeon that things are going wrong in time for the latter to apply successful resuscitatory measures.

At the first sign of cardiac arrest (in abdominal operations this is best confirmed by palpating the aorta), the head should be lowered, coramine injected, and the chest slapped, or forcibly compressed over the precordia and suddenly released. If there is no response in under a minute, one or two cc. of 1 in 1000 adrenalin should be injected into the right ventricle through the fourth intercostal space. When the abdomen is open, cardiac massage should be started at once by the surgeon, while his assistants carry out the above measures and

apply artificial respiration; otherwise a left paramedian epigastric incision is made at maximum speed. The right hand is insinuated above the left lobe of the liver, and the heart squeezed rhythmically and methodically through the diaphragm, the precordial region being steadied with the left hand. The adrenalin may be injected through the diaphragm, as it is then more likely to reach the heart muscle instead of being wasted in a cardiac chamber.

The diaphragm should never be incised in performing cardiac massage, and care must be taken not to tear the liver or its ligaments. The trans-thoracic approach is not permissible, as there is never enough time to allow of it. To stand any chance of success the surgeon should be massaging the heart within five minutes of its arrest; the brain centres will not recover after a much longer period of anoxæmia, even if the heart be coaxed to a short return of function.

CHAPTER II

Surgery of the Veins

VARICOSE VEINS

Ætiology and Morbid Anatomy.

The veins of the lower extremity are arranged in three sets, superficial, deep, and communicating. Of the *superficial veins*, the *long* or *internal saphenous* runs up the inner side of the leg and thigh, to pierce the deep fascia at the saphenous opening, and open into the femoral vein; the *short* or *external saphenous* runs up the postero-external aspect of the leg and enters the popliteal vein. The *deep veins* start as venæ comites accompanying the arteries of the foot and leg, and join to form the popliteal vein, which continues up as the femoral vein. The *communicating veins* perforate the deep fascia of the leg and thigh at intervals, and establish free communications between the superficial and deep veins. All three sets of veins are supplied with valves which, when competent, prevent reversal of the normal direction of the blood-flow.

The upward flow of venous blood is opposed by gravity. With such a long column of blood as is represented by the distance between the feet and diaphragm, the factors responsible for the maintenance of the venous flow operate at considerable disadvantage in the erect posture. This applies particularly to the small propulsive force represented by the difference between capillary and venous pressure, and to the suction effect of the negative pressure in the great veins produced by respiratory and cardiac activity. Indeed, in the upright position, the upward flow of venous blood depends mainly on the contraction of the lower limb muscles. Such contraction pushes the blood in the deep veins upwards, and thus sucks the blood out of the superficial veins, through their junction with the main venous trunks. and also through the communicating veins. For this mechanism to function properly it is obvious that the valves in all three sets of veins must be competent, and that the erect posture, when kept up for lengthy periods, must be combined with muscular exercise.

Recent work with radio-opaque injections by Barber and Orley tends to show that blood does not enter the deep veins through the communicating channels, but as their experiments were performed

on the X-ray table they do not invalidate the above description, which refers to the mechanism of the venous flow under conditions of postural stress.

In the *ætiology* of varicose veins several factors play a part. The chief of these is *venous stasis*, mostly caused by long periods of standing in people of otherwise sedentary habit. The deep veins, well supported by surrounding muscles, are protected from the effects of this stasis, but the superficial veins feel the full brunt of it. Being quite unsupported, and deprived of the suction effect of adequate muscular contraction, they begin to distend with accumulated blood. The rise in intravenous pressure is at first compensated by hypertrophy of the scanty muscular and elastic tissues of the venous wall, and while the valves remain competent the veins may regain their normal size and efficiency if the factors responsible for the stasis are arrested. Continuation of the unfavourable conditions, however, ultimately leads to *incompetence of the valves*, owing to venous distension beyond the limits of valvular closure. A vicious circle is now initiated, more and more valves fail, and the dilated veins lengthen, become tortuous, and undergo degenerative and fibrotic changes in their walls; in other words, they become varicose, and the dilatation is now permanent (phlebectasis). All the layers of the vein wall share in these degenerative changes: the *intima* becomes irregular and loses its resistance to stress, so that thrombosis and phlebitis may result; the *media* becomes thick, and more and more fibrous and rigid, although it is sometimes atrophied and thin; the *adventitia* is involved in the fibrotic process, which may spread beyond the vein and cause it to adhere to the skin.

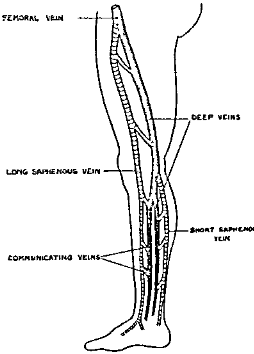

Fig 2188.—Scheme of veins of lower limb.

The superficial veins are no longer able to function properly, and, in the effort to regain efficiency, they may develop into great loops or bundles of vessels, often very thick-walled, but sometimes thin-walled in places. Adjacent loops may communicate to form large venous sinuses, and various morbid changes occur in the veins themselves, and

in the skin and other tissues which they drain. The limb becomes congested and waterlogged, and suffers the effects of blood stagnation. These morbid changes are made worse by involvement of the communicating veins in the varicose process, and by incompetence of their valves.

Two conditions which may be associated with venous stasis, and to which the writer drew attention in a recent paper, are *senile phlebosclerosis and periphlebitis.* The first is a fibrotic hardening of the veins, mostly seen in elderly patients with chronic ulcer of the leg, and occurring quite apart from varices. Periphlebitis is a cellular infiltration of the perivenous tissues which occasionally develops as a result of venous stasis, and is also seen in chronic leg ulcers; the vein itself remains thin-walled and can be felt as a fluid line, sunk into the infiltrated area.

Inherited predisposition also plays an important part in ætiology, and according to Ochsner it can be demonstrated in 75 per cent of cases; not infrequently varicose veins are associated with varicosities elsewhere, e.g. varicocele, hæmorrhoids, etc. This inherited weakness of the vein wall explains the extensive varices sometimes seen in young people, but when the condition occurs in later life it is mostly mechanical in origin. Furthermore, it is significant that phlebectasis and phlebosclerosis may be accompanied by sclerosis of the arteries.

Quite distinct in causation are the varices produced by the pressure of the *gravid uterus*, and of abdominal or pelvic *tumours*, on the iliac veins, and those which form to compensate *thrombosis of deep veins.* The varicose veins of pregnancy cannot be entirely caused by pressure, as they often develop in the early months and may be very widespread.

Clinical Features.

Varicose veins are seen at all ages, but mostly in young adults and middle-aged people. The long saphenous tract is involved in the vast majority, mostly below the knee, but often in the thigh as well; the short saphenous suffers much less, but frequently shows some varicosities. The degree of involvement varies enormously. There may be just a few cyst-like dilatations in the course of the long saphenous: the whole vein may be more or less evenly dilated without bunching or looping; or there may be great tortuosity with masses and loops of distended veins and sinuses. The condition may be limited to the larger veins, or it may involve the small radicles; dilatation of the venules of the skin is responsible for unsightly spider-like and other markings, but is otherwise of no importance.

Many patients experience no symptoms whatever, but seek treatment merely because they have varicose veins. More than half, however,

complain of a heavy *aching* in the legs, and of *fatigue* which comes on with undue rapidity. Occasionally, severe *cramp-like pains* occur which may be caused by inadequacy of the nervous blood supply.

The results of *blood stagnation* then manifest themselves. There is a fall in the oxygen of the local venous blood, and a rise in CO_2, urea, and non-protein nitrogen. The resulting anoxæmia sets up an irritating *dermatitis*, with itching, and areas of *pigmentation*, especially above the internal malleolus. The limb becomes *œdematous* and waterlogged, *lymphatic stasis* ensues and leads to *hypertrophic and sclerotic processes* in the skin, the subcutis and other tissues, and a more or less extensive *ulceration* may be the final result. Another possible sequel is *hæmorrhage* owing to rupture of the atrophied skin over an adherent vein.

Investigations.

Before undertaking treatment, the surgeon should ascertain if the valves in the superficial and communicating veins are competent or not, and if the deep veins are patent or not.

The competency of the superficial veins is determined by *Trendelenburg's test*, to which attention has recently (1934) been drawn by Cooper. With the patient standing, the lower end of the saphenous vein in the thigh is compressed with the thumb, and the blood in it milked upwards: if the vein remains collapsed, the valves are competent and the test is negative; if the vein fills from above, the valves are incompetent and Trendelenburg's sign is positive. The competency of the communicating valves is examined by *Perthé's test*. The saphenous vein is obliterated in the thigh with a blood-pressure cuff, and the patient made to walk about; the muscular activity should suck the blood out of the superficial veins, but if the valves in the communicating veins are incompetent the superficial veins remain full.

To test the *patency of the deep veins*, the superficial veins are obliterated with an elastic bandage from the toes to the knee; the patient is then made to walk for half an hour. If the deep veins are patent, the patient remains quite comfortable and any previous pain subsides, but when the deep veins are thrombosed, the patient will complain of increasing discomfort. The importance of determining the patency of the deep veins is quite obvious, as any attempt to obliterate the superficial veins by injections or other treatment will have disastrous consequences in the presence of deep thrombosis.

Complications.

Numerous morbid conditions occur in association with varicose veins, but they are dependent, not on the varices, but on the venous

in the skin and other tissues which they drain. The limb becomes congested and waterlogged, and suffers the effects of blood stagnation. These *morbid changes are made worse by involvement of the communicating* veins in the varicose process, and by incompetence of their valves.

Two conditions which may be associated with venous stasis, and to which the writer drew attention in a recent paper, are *senile phlebosclerosis and periphlebitis.* The first is a fibrotic hardening of the veins, mostly seen in elderly patients with chronic ulcer of the leg, and occurring quite apart from varices. The importance of determining the patency of the deep veins is quite obvious, as any attempt to obliterate the superficial veins by injections or other treatment will have disastrous consequences in the presence of deep thrombosis.

Complications.

Numerous morbid conditions occur in association with varicose veins, but they are dependent, not on the varices, but on the venous

stasis. the blood stagnation. and the resulting local anoxæmia, accumulation of toxic metabolites, and local tissue acidosis.

Associated *skin* changes are perhaps the most striking. *Eczematous dermatitis* (varicose eczema) is a common result and is seen in various types—erythematous, scaly, and weeping; it may be localised, or it may involve the whole of what is known as the "ulcer-bearing area" of the leg (fig. 2189). *Pigmentation* (fig. 2190) occurs in the form of brownish macules which coalesce to form large areas of discolouration, and which may ultimately also occupy the whole of the "ulcer-bearing"

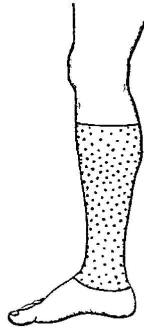

Fig 2189.—Ulcer-bearing area.

Fig 2190.—Chronic ulcer of leg with eczema and pigmentation.
(By kind permission of the "Lancet.")

area. *Pruritus* is very common, and *dermatitis artefacta* may result from scratching. Other common results are *alopecia*, and a *dry* and *hypertrophied skin*.

Œdema of the ankle and lower part of the leg occurs in advanced cases, but quite distinct from this is a *brawny swelling* of the limb which is sometimes seen, and which is caused by hypertrophy of the subcutaneous and deeper areolar tissues owing to lymph stasis. An interesting result of the local hyperæmia, and one to which attention has only recently been drawn, is a *decalcification* of the lower part of the leg bones. *Hæmorrhage* from a ruptured varicose vein has been mentioned already; it is frequently started by injury, and, although easily controlled, it may proceed to an alarming and even fatal degree if unintelligent first-aid measures are employed.

Perhaps the most interesting result of venous stasis is *chronic ulcer* of the leg (fig. 2190). This is a typical indolent and spreading ulcer, often severely painful, and occurring anywhere in the ulcer-bearing area (fig. 2191). It is extremely chronic, starts mostly after the fourth decade, and may grow to a huge size (up to 40 square inches or more). Of 144 cases of indolent ulcer reported by the writer in 1933, only 90 (62·5 per cent) were associated with varicose veins; in the remainder no varices were observed. It follows that varicosity is by no means an

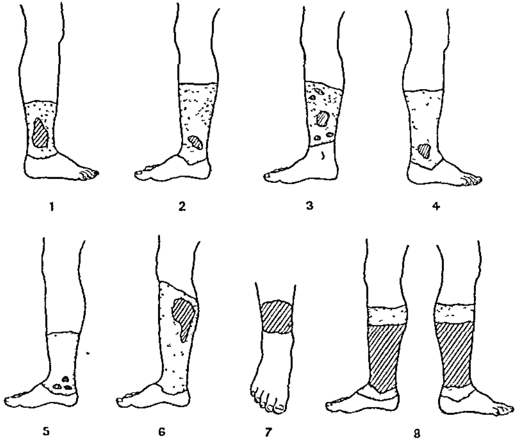

Fig. 2191.—Diagrammatic record of 8 cases of varicose ulcer and eczema.

invariable factor in the causation of the wrongly termed "varicose ulcer"; the essential cause is venous stasis.

There can be no question that varicose veins are liable to attacks of *thrombophlebitis*, but owing to reversal of the blood stream *embolism* is a very rare complication.

Treatment.

For some years varicose veins have been universally treated by the *intravenous injection* of sclerosing substances. The great advantages of this method are that it is extremely safe, and that it does not interfere

with the patient's ordinary life and occupation. The substances mostly used to-day are sodium morrhuate, sodium salicylate, lithium salicylate, and quinine and urethane. They act by damaging the intima, which becomes irregular and "sticky." Thrombosis occurs and plays a part in the early obliteration of the veins, but final obliteration is produced either by organisation of the thrombus or by an adhesive endophlebitis ending in fibrous sclerosis of the vessel. Adhesive obliteration is more permanent than thrombosis as there is less likelihood of recanalisation of the veins. Experimental work shows that destruction of the endothelium reaches its maximum on the fourth or fifth day, while on the sixth or seventh day regeneration begins. This suggests that the injections should be given every five or six days.

Detailed consideration of the *injection treatment* is given in another section of this work (see Vol. II, page 3281), but certain general points may be dealt with here. The most obvious point is that before treatment is started we must make certain that the deep veins are patent; thrombosis in these is an absolute contra-indication to injections. Other *contra-indications* are advanced arterial disease and infective thrombophlebitis; in the former are included thrombo-angeitis and severe arteriosclerosis, in both of which intravenous injections may be the determining cause of gangrene: in thrombophlebitis of infective origin the injection may result in exacerbations of the phlebitis and possibly in *embolism*. Although embolism is an extremely rare complication of injection treatment (Ochsner was only able to collect twenty-eight cases from the literature up to 1932), most cases occur in thrombophlebitic veins.

Of recent years the injection treatment of varicose veins has been the subject of considerable criticism. In the opinion of many there is a high incidence of recurrence, and there is a large group of cases in which injections fail unless they are combined with simultaneous *ligature* of one or more veins. In the last group the valves are incompetent, as shown by the Trendelenburg sign, and the saphenous vein must be ligated at the highest palpable point, before injections are started. This small operation is performed under local anæsthesia, and the patient is allowed to get about at once. Patey recommends *excision* of the long saphenous in the thigh by Babcock's subcutaneous method, by which the vein is divided high up and tied to a special probe, which is pushed down and made to emerge through a small incision lower down; the vein is now pulled out, its tributaries tearing without hæmorrhage, and excised. An injection of 5 cc. of sodium morrhuate is given into the distal end of the vein and the leg bandaged with elastoplast, which is left un-

disturbed for ten days. This procedure is often successful when simple injections fail, and is probably the best treatment for cases with extensive varicose veins involving the thigh as well as the leg. Numerous other operations, once frequently performed, are practically obsolete now.

When the Trendelenburg sign is negative, i.e. when the valves are still competent, injections alone will probably succeed in obliterating most of the varices, but it may be necessary to repeat the treatment after some years.

THROMBOPHLEBITIS

The term thrombophlebitis implies inflammation of a vein and clotting of its contained blood. It is in no sense a clinical or even a pathological entity, but must be regarded as a descriptive term which covers a large number of more or less distinct conditions, conveniently grouped together within the limits of the above definition. With the object of avoiding unnecessary overlapping and repetition, the various conditions will be dealt with here as a group, but it should be observed that they differ considerably in their pathology, clinical manifestations, complications and treatment. The one common factor is that all forms of thrombophlebitis start as an inflammatory lesion of the vein wall, and that thrombosis follows changes in the venous endothelium caused by the inflammation.

Classification and Ætiology.

The large number and variety of lesions grouped under the term thrombophlebitis is shown by the use of such descriptive terms as post-operative thrombosis, puerperal thrombosis, leukæmic thrombosis, pylephlebitis, familial phlebitis, traumatic phlebitis, deep vein thrombosis, superficial phlebitis, sinus thrombosis, phlebitis migrans, essential thrombophilia, etc. A consideration of these lesions on an ætiological basis shows that four factors operate in the causation of thrombophlebitis: (1) infection or other disease of the vein wall, (2) trauma, (3) venous stasis, and (4) altered state of the blood.

(1) *Infection of the vein wall* may be the result of *spread* from a neighbouring *septic focus*. Examples of this are: (*a*) *Pylephlebitis*, in which the mesenteric and portal veins become the site of a suppurative thrombosis, spreading from a septic focus such as the appendix or a sloughing hæmorrhoid, and ending in a portal pyæmia with multiple liver abscesses; (*b*) *lateral sinus thrombosis* (fig. 2192), in which the infection reaches the sinus from the tympano-mastoid cavity, and spreads as a suppurative phlebitis down the jugular vein; (*c*) *cavernous sinus thrombosis*, a very fatal condition produced by spread of pyogenic infection from the upper lip or nose, along the angular vein, or from the

orbit, along the ophthalmic veins; (*d*) *acute osteomyelitis*, commonly associated with a septic thrombosis of the veins in the bone-marrow and Haversian systems, which is particularly dangerous as the veins are held open by adhesion of their walls to the rigid vascular canals; and (*e*) *puerperal thrombosis* of the pelvic and iliac veins, which is a common result of infected labour or abortion. All these varieties of thrombophlebitis are *suppurative*, and can be produced by infection without stasis. They are all extremely dangerous to life, inasmuch as they are frequently responsible for the development of *pyæmia*.

Infective thrombophlebitis also occurs in the course of certain

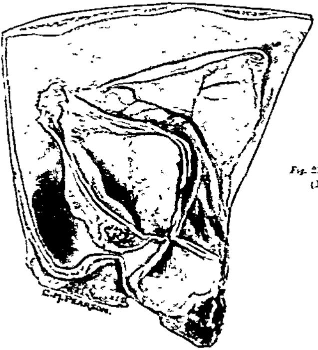

Fig. 2192.—Lateral sinus thrombosis. (*Museum, St. Mary's Hospital.*)

specific fevers, particularly *typhoid*, *pneumonia*, *influenza* and *malaria*. Here, although infection probably plays the larger part, stasis and an altered character of the blood are additional ætiological factors. The phlebitis is usually non-suppurative.

(2) *Trauma* causes a thrombophlebitis which may or may not be infective. In a recent discussion (1936) Dickson Wright drew attention to the thrombosis that frequently accompanies *fractures* of the leg, thigh and pelvis, and to *traumatic axillary phlebitis*, which he attributed to occupations entailing weight-lifting or downward snatching of heavy objects. Infective thrombophlebitis may be caused by *direct infection* through an open wound, by a sting or bite, or from *contaminated injections* for varicose veins.

(3) *Venous stasis* does not in itself produce thrombosis, but it acts as a common and important contributory cause, particularly in *post-operative thrombophlebitis.* According to Ochsner, it is slowing up of the stream, with eddying of blood in the veins, rather than complete arrest, that favours thrombosis; but the direct cause is almost certainly infective. More than 80 per cent of cases of post-operative thrombosis follow operations on the abdomen, particularly on the appendix, gall-bladder and pelvic organs. The stasis of *varicose veins* is another common cause of thrombophlebitis, which in this case is

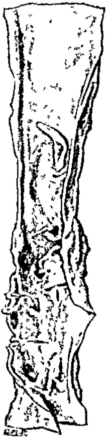

Fig 2193.—Thrombophlebitis of femoral vein. (*Museum, Royal College of Surgeons.*)

Fig 2194.—Thrombosis of femoral vein (*Museum, Royal College of Surgeons*)

usually *superficial. Mechanical obstruction* and *circulatory weakness* are further ætiological factors which operate by causing stasis.

(4) An *altered state of the blood* is responsible for the thrombosis of *leukæmia* and *essential thrombophilia.* It may also account for the cases of *familial phlebitis,* and possibly for the thrombosis that occasionally occurs in syphilis, gout and tuberculosis, although in these *endophlebitis* may be the main causal factor.

Morbid Anatomy (fig. 2193).

This will vary according to the suppurative or non-suppurative character of the inflammation, the variety of the infecting organisms,

thrombosis spreads from the iliac to the femoral vein; Homans believes that the outward spread of the phlebitis obstructs the perivenous lymph channels, but Zimmermann and de Takatz maintain that the perivenous lymphatics are patent, and that the curious nature of the œdema is due to escape of fluid very rich in proteins, owing to extreme permeability of the vessel walls.

The *resolution* of thrombophlebitis comes by subsidence of inflammation and organisation of the clot. Capillary loops grow in from the vasa vasorum in the vein wall and form a cellular granulation tissue which attacks the thrombus and organises it into fibrous tissue. The fibrosis may be complete and lead to permanent obliteration of the vein, which is converted into a solid cord; or part of the lumen may be left, and the shrunken and fibrosed clot become covered with endothelium, thus partly reconstituting the venous channel. Old thrombi are often *calcified by deposition of lime salts, to form phleboliths*; these are prone to develop in varicose veins, usually near a valve.

Clinical Features.

These again are extremely variable. Some *constitutional disturbance* is usual, but it will vary from a mild fever with slight malaise, to a high swinging temperature, with rigors and other symptoms of pyæmia. Leucocytosis is common, especially when deep veins are affected.

The *local symptoms and signs* are obvious in superficial phlebitis, but may be very obscure in deep-seated venous infection. *Pain* is constant; it is of a dull, throbbing nature, and is made worse by movement. There is *tenderness* along the course of the vein, which, if accessible, can often be palpated as a *hard cord*. In superficial phlebitis, mostly affecting the saphenous veins, there is marked *redness*, infiltration and tenderness along the course of the vein. Pitting *œdema* is a prominent symptom, especially in deep thrombosis, in which also there may be *dilation of superficial veins*, and considerable *loss of muscular function*. Occasionally there is some congestion or cyanosis of the skin, and its temperature is sometimes raised by as much as two or three degrees Centigrade.

Prognosis and Complications.

The *prognosis* varies with the site, cause, and virulence of the infection, and the resistance of the patient. It is excellent in superficial and traumatic phlebitis, good in post-operative thrombosis, serious in lateral sinus infection, osteomyelitis and all forms of suppurative thrombosis, and very bad in cavernous sinus thrombosis, pylephlebitis, and puerperal thrombophlebitis.

The most serious *complication* is *pyæmia*, whether this is systemic or portal. Massive *pulmonary embolism* is a less common but even more fatal complication. Less serious forms of *embolism* also occur, and they may cause *infarction* or *metastatic infections*, without a generalised pyæmia; thus, small emboli may lodge in the lungs and cause single or multiple *pulmonary infarcts*, often diagnosed as pneumonia, especially when they occur after operations.

Another complication is *persistent œdema*, which is an occasional result of axillary thrombophlebitis, but is more often seen after a femoral thrombosis. It is probably caused by a combined venous and lymphatic obstruction.

Treatment.

Only general principles can be dealt with here, but a more detailed description will be found under special types of phlebitis. *Prophylactic treatment* is of the utmost value and may be summed up in one sentence: avoid infection and trauma, and prevent venous stagnation. This particularly applies to abdominal operations, where absolute asepsis and gentle manipulation will do much to diminish the incidence of post-operative femoral thrombosis. It is well known that rough manipulation of the abdominal wall is likely to injure the deep epigastric veins, and that this may initiate a thrombophlebitis which spreads to the femoral vein. Avoidance of post-operative stagnation is equally important: early sitting up, deep breathing, and bed exercises will do a great deal in this direction. The blood stream can be accelerated by judicious administration of thyroid extract. Attention has recently been drawn to the value of a high protein diet, especially in patients with a personal or family history of phlebitis. Thrombophlebitis in varicose veins may be prevented by controlling venous stasis with exercise and elastic support.

The treatment of *established* thrombophlebitis is carried out mainly along *conservative* lines. In general, it consists of absolute rest of the limb, elevation, and an ample cotton-wool dressing, with a cradle to keep the limb warm and protect it from injury. For phlebitis below the knee, firm support with elastoplast bandages undoubtedly shortens the course of the disease and diminishes the tendency to upward spread. The duration of the rest period varies with the vein involved, but in general it should continue until all constitutional and local signs of inflammation have completely disappeared.

Constitutional measures are of doubtful value, apart perhaps from *thyroid* therapy, which appears to have a definite influence in limiting the spread of post-operative thrombosis. It is quite usual to give large

doses of *citrate,* but it has recently been suggested that *in vivo* citrate increases instead of diminishes the coagulability of venous blood. There can be no doubt, however, that coagulability is lowered by *hirudin,* and, based on this fact, the leech treatment of phlebitis has recently been revived. Used carefully, this does seem to relieve pain and œdema, but it is doubtful if it exerts any lasting effect on the lesion.

Operative treatment is indicated as a life-saving measure in *acute pyogenic thrombophlebitis,* its object being to avert pyæmia and metastatic embolism. It is usually wise to remove or drain the *infecting focus,* e.g. the appendix in pylephlebitis, or the mastoid in lateral sinus thrombosis; but there is one region where active surgical intervention is to be strongly deprecated, and that is the territory drained by the *cavernous sinus.* This particularly applies to infections of the *upper lip,* in which muscular activity, and the inability of the veins to collapse, make an ascending thrombophlebitis, with extension to the cavernous sinus, particularly likely. The writer has seen four fatal cases of cavernous sinus thrombosis result from septic lesions of the upper lip which were treated by free incision and drainage.

Proximal ligature of the vein, well to the cardiac side of the thrombus, is a valuable procedure in some cases, and has been in use since the middle of the last century. It has been practised on the following veins: jugular, angular (facial), femoral, axillary, mesenteric, iliac and ovarian. Although occasionally performed for non-suppurative thrombosis of both superficial and deep veins, we feel strongly that it should be reserved for cases of *suppurative thrombophlebitis,* its sole object being to prevent pyæmia and septic embolism. The value of ligature and drainage of the internal jugular vein in the neck for lateral sinus thrombosis is beyond dispute, and there can be no doubt that suppurative thrombophlebitis in the limbs should also be treated by proximal ligature, with free opening of the vein and turning out of the infected clot. Ligature of the angular vein, with the object of protecting the cavernous sinus in infections of the face, is of more doubtful usefulness, but it is certainly worth trying. The same applies to ligature of the portal and mesenteric veins, although here the chief difficulty lies in getting above the pus. The writer has had no experience of proximal ligature for puerperal pelvic thrombosis, but the procedure has been recommended for cases which have recovered from the acute stage; best results are said to be obtained when both ovarian and both internal iliac veins have been ligated.

Quite recently, Neuhof advised complete *excision* of accessible veins which are the site of septic thrombophlebitis, on the ground that

proximal ligation is a temporising method, and that complete eradication of the infected vein gives the best hope of avoiding pyæmia or septicæmia, and of saving life when these blood infections have become established.

SOME SPECIAL TYPES OF THROMBOPHLEBITIS

Traumatic Thrombophlebitis of Axillary Vein.

First recognised some fifty years ago, this condition has attracted considerable interest recently. Although there may be a predisposing cause, such as essential or familial thrombophilia, there can be no doubt that the condition is traumatic in origin. As already mentioned, weight-lifting or downward snatching of heavy objects are types of causative muscular trauma, but in some cases quite trivial muscular effort seems to be responsible. It has been suggested that the pull of the subclavius, with the arm in abduction, may rupture a valve or damage the intima, and that endophlebitis and thrombosis result. The writer recently saw a case in which there was no history of preceding trauma.

The right arm is affected almost exclusively, and the attack usually starts quite suddenly with pain and complete disability, immediately or shortly after a muscular effort. Swelling and cyanosis of the arm follow, although in some cases there is pallor. The swelling is firm and spreads to the whole limb. Sometimes a tender solid cord may be palpated in the axilla. but there is no fever or signs of inflammation.

The duration of the attack is usually a few weeks, but recurrence is not uncommon and persistent œdema may be the ultimate result. The *treatment* consists of rest, elevation, and proper support with an elastoplast bandage from the hand to the axilla. Should the condition persist or recur, Matas advises exploration of the axillary vein and resection of the thrombosed segment; he attributes the good results to vasodilatation of the vein produced by removal of the sympathetic plexus around the resected segment.

Deep Thrombophlebitis of Leg.

Femoral thrombophlebitis has been dealt with in some detail already (see Vol. I, page 1256). It is encountered as a *post-operative* complication, in *puerperal* infections, following *specific fevers*, and as an *ascending thrombosis* from the deep or superficial veins of the leg. The left side is more commonly affected, because venous stasis is favoured by the fact that the left iliac vein is crossed by the right iliac artery, and also because the left iliac vein is covered by the sigmoid colon. Although usually of infective origin, femoral thrombosis is mostly non-

suppurative. Diagnosis is rarely difficult, and treatment is conducted along the lines given on page 4002.

Thrombophlebitis of the tibial veins is treated in a similar way, but upward extension may be stopped by firmly bandaging the limb from the toes to the groin with elastoplast. Provided this precautionary measure has been successful, the patient may be allowed to get about after two or three weeks, but the elastoplast should be continued whilst any swelling remains.

Superficial Phlebitis of Leg.

This is mostly seen in varicose veins, particularly in the *long saphenous*, and there can be little doubt that some cases can be attributed to injection treatment, the sclerosing agent lighting up dormant bacterial infection. According to Dickson Wright, the condition is sometimes due to focal sepsis, and he discriminates between a mild or localised type and an ascending type. *Diagnosis* is easily made. There is little general reaction, and the local signs (pain, tenderness and redness) are usually quite obvious; the thrombosed veins can be felt as tender cords. There is little œdema unless the deep veins are involved as well, which is an unlikely event.

The *treatment* is governed by the fact that superficial phlebitis is a safe lesion in an ambulant patient, but becomes dangerous when the patient stays in bed (Dickson Wright). The affected veins should be firmly strapped with elastoplast, under which rubber sponges should be applied at the upper end of the thrombi, to prevent the clot from slipping upwards. Moderate exercise is encouraged from the start. The attack may be expected to subside within a fortnight.

Phlebitis of the *external saphenous* is more dangerous, as it is more likely to spread to the deep veins via its junction with the popliteal vein. For this reason, ligature of the vein, just before it pierces the popliteal fascia, may be worthy of consideration.

Thrombophlebitis Migrans.

Recognised only in the last few years, this condition is of considerable interest. Thrombophlebitis occurs in various veins, together or successively, but with no obvious relationship. It can be an extremely painful condition, and large doses of morphine may be needed to give relief. Pulmonary complications sometimes occur from thrombophlebitis of small pulmonary veins. No organisms are found, and the condition is not unlike Buerger's thrombo-angeitis obliterans; indeed, it is sometimes associated with it.

The disease never seems to be fatal, and complete recovery is the rule, but some cases seem to drag on for months, or even years. Such cases might be greatly benefited by a holiday, or by spa treatment.

CHAPTER III

Injuries and Surgical Diseases of Arteries

Arterial Injuries

Arterial injuries vary from a contusion to a complete rupture or division. They may be open or subcutaneous. An arterial wound can be incomplete or complete, transverse or longitudinal, clean cut or lacerated. The injured artery may be small, medium-sized, or large. The arterial injury can be associated with fatal hæmorrhage, with negligible hæmorrhage, or with no hæmorrhage at all. The injury may involve the artery alone, it may implicate the accompanying vein, or it may also involve other tissues, such as nerves, tendons, bones, joints and viscera. It is thus obvious that it is almost impossible to deal with arterial injuries as a single clinical entity. Since the subject is described very adequately in elementary surgical text-books, it will not here be necessary to do more than remind the reader of certain fundamental principles, and to deal with those aspects of pathology and treatment which are properly discussed in an advanced text-book.

A *contusion* of an artery is of little consequence in the absence of arterial disease, as a healthy elastic vessel will slip out of the way, or simply alter its shape before a causative violence. An artery which is the seat of thrombo-angeitis or arteriosclerosis, however, is likely to be damaged, with the result that a *thrombosis* is initiated; even slight injuries may have this effect on a severely diseased vessel.

A *clean-cut transverse wound* of an artery of some size is associated with alarming hæmorrhage (fig. 2195). The bleeding is often worse if such a wound is *incomplete*, since the retraction of the elastic tissue and the contraction of the arterial muscle pull the wound open. With a *complete* transverse division the intima and media are at least able to contract and retract within the adventitia, and by markedly narrowing the lumen and providing rough surfaces give a chance for clotting to occur. In smaller arteries this natural process may result in early

arrest of the hæmorrhage, but in larger vessels the force of the arterial stream is too great to be stopped by it. When an artery is divided near its origin from a larger trunk, it bleeds with the force of the blood-pressure in the main vessel.

A wound in the *long axis* of an artery gapes but little and only slight bleeding may occur. The result of a *punctured wound* of an artery depends on the nature of the penetrating body. A stab wound, e.g. with a penknife or a glass splinter, causes extravasation and an arterial hæmatoma, with or without external evidence of bleeding; the skin

Fig. 2195.—Transverse incised wound of femoral artery. (*Museum, Royal College of Surgeons.*)

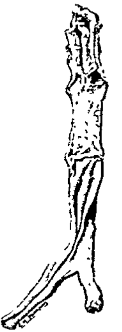

Fig. 2196.—Subadventitial rupture of artery. (*Museum, St. Mary's Hospital.*)

wound may be valvular, or become closed by clot or by shifting of tissue planes. If hæmorrhage ceases, the arterial wound may heal and the integrity of the artery be restored, but the scar is likely to yield later and produce a traumatic aneurysm. The same kind of thing may happen when an artery is injured by a modern bullet or by shell fragments, the resulting aneurysm being frequently of the traumatic arterial or arterio-venous type.

A *lacerated rupture* of an artery, such as occurs in a severe lacerated wound, or when a portion of the vessel is torn off, or the limb is avulsed, may be associated with comparatively little bleeding, even when the artery is of some size. The reason for this is that the intima and media

tear at a higher level than the adventitia, retracting some distance, and that the periarterial tissues close up over them. An intense reflex vasoconstriction also occurs in the torn artery, and chemical bodies are set free which favour clotting. These factors constitute a very efficient hæmostatic mechanism. Thus, the writer has seen the common femoral torn across in a boy who was impaled on some railings, with negligible bleeding, and with such marked retraction of the ends that they were well over an inch apart.

A *subcutaneous rupture* of an artery is caused by blows, severe traction, or by an injury causing a fracture or dislocation. Only the intima and media may give way, retracting within the adventitia for a considerable distance (fig. 2196); such a *partial rupture* will be followed by thrombosis and occlusion of the vessel. When only one side of the arterial wall is injured, the thrombosis may be limited to the injured part, and the lumen reconstituted by a growth of endothelium over the organised thrombus; this type of injury is likely to be followed by a traumatic, sacculated or dissecting aneurysm. A *complete* subcutaneous rupture of an artery of some size is always followed by extravasation of blood. When this rupture occurs within a body cavity, such as the pleura, peritoneum, or a hollow viscus, *concealed* or *internal hæmorrhage* occurs and may prove fatal. Rupture of more superficial arteries leads to the formation of an *arterial hæmatoma*, which is a rapidly enlarging swelling on the line of an artery, and showing an expansile pulsation. Such a hæmatoma soon compresses the neighbouring veins and the collateral arteries, thus endangering the vitality of the tissues of the part, and perhaps terminating in *gangrene*. The hæmatoma may *rupture* or *suppurate*, in either case possibly leading to a fatal result; not infrequently it becomes circumscribed, and if the artery is not completely occluded, a *traumatic aneurysm* may be the outcome.

Treatment.

The first step in the treatment of a wounded or ruptured artery is *temporary arrest of hæmorrhage*. The general principles may be summarised here: *Direct digital pressure* is applied to the source of bleeding, while the surgeon decides what method to employ for the temporary proximal compression of the artery. In the head and neck, and in the more proximal parts of the limbs (axilla and groin), the best procedure is manual or digital compression of the arterial trunk against a bony structure, e.g. the sixth cervical transverse process for the carotid, the first rib for the subclavian, etc. This *proximal compression* is given over to an assistant, while the surgeon prepares to deal with the arterial injury

itself. In the free parts of the limbs the simplest and most efficient agent of temporary arrest is a *tourniquet*, but it is very important that this should not be kept on for more than a very short period (half an hour at most), unless amputation is unavoidable; if continued for longer periods it may cause serious damage by shutting off collateral vessels, with an increased risk of gangrene when a main artery has to be ligated.

In the actual *treatment of the arterial wound* the first step is exposure of the wounded vessel. An adequate and well-planned incision, a sound knowledge of anatomy, efficient lighting, absolute asepsis, and a non-mutilating approach are essential. With a subcutaneous rupture all clots must be turned out and the region thoroughly cleansed before the arterial wound is sought for; in an open or penetrating wound there may also be a considerable extravasation into the tissues, which will have to be dealt with in the same way.

The second step is permanent arrest of hæmorrhage and treatment of the wounded artery. For this purpose two procedures are available, arterial suture and ligature. *Arterial suture* is, of course, the ideal procedure, and should be employed, whenever possible, in wounding of a large or important artery, such as the common carotid, external iliac, femoral or popliteal. Modern methods have made suture a practical and frequently successful operation. It is particularly suitable for longitudinal and transverse wounds which do not completely divide the artery (lateral suture), but under favourable conditions can also be employed for a complete rupture or division of a large artery (*end-to-end anastomosis*). The technique of arterial suture is given in a later part of this section (see page 4083).

Although an ideal procedure, arterial suture can only be undertaken by an expert surgeon, and is only applicable in special cases. The large majority of arterial wounds and ruptures have still to be treated by *ligature*. This is definitely indicated in injuries of smaller and relatively unimportant vessels, and will have to be resorted to in large arteries when suture cannot be effected, or when this fails. Ligature must be performed at the actual site of the arterial injury; proximal ligation often fails to arrest bleeding, owing to the presence of collateral branches between the ligature and the wound. When an artery is not completely divided, the vessel must be ligated above and below the injured segment, and the division completed by the surgeon, so that the two ends can retract. In a complete division or rupture, *both ends* must be found and ligatured, as serious *hæmorrhage* may occur from the distal end when the collateral circulation becomes established. The upper end of the

artery is found with little difficulty, its pulsations acting as a guide, but the distal end may need a good deal of searching for. Having dealt with the injured artery, the surgeon should carefully search for injuries of other vessels, or of neighbouring structures, such as nerves and tendons. After ligature of an important vessel a careful watch must be kept on the circulation in the tissues it supplies, and every possible care taken to avoid such complications as ischæmic myositis, gangrene, and secondary hæmorrhage.

For details and technique of arterial ligature the reader is referred to page 4085.

Arterial Thrombosis

Thrombosis rarely occurs in a healthy and uninjured artery. Attention has recently been drawn to the occurrence of a cyclic thrombosis in apparently quite healthy arteries and veins, which is due to an unexplained periodic increase of the coagulability of the plasma. The disease has been called *essential thrombophilia,* but so far as we know at present it is extremely rare.

Ordinarily, thrombosis in an artery is either primary or secondary. *Secondary thrombosis* occurs in a vessel already occluded by an embolus, which is usually a piece of blood clot brought from a more proximal part of the circulation ; the occluded vessel may or may not be diseased, but the thrombosis occurring locally is merely a process of clotting spreading from the embolus. Such thrombosis may extend both proximally and distally, and may involve collateral branches of the occluded artery. *Primary thrombosis* is essentially caused by *injury* or *disease* of the *intima* of an artery which has implicated the endothelial layer. Arterial occlusion, whether by ligature, vasospasm or disease, will not of itself cause thrombosis, if the intimal endothelium remains intact. Injuries act by producing rupture of the intima, and thrombosis is likely to result whether such rupture be partial or complete. Arterial disease (arteritis, thrombo-angeitis, or arteriosclerosis) causes thrombosis by ulceration or roughening of the intima.

In the presence of intimal damage, thrombosis is further predisposed to by infection (local or general), by slowing of the blood stream, and by increased viscosity or coagulability of the blood. In the limbs, these predisposing and actual causes of thrombosis are usually supplied by local arterial disease, but thrombosis of other arteries is sometimes attributable to systemic causes, such as protein shock, acute infective diseases and polycythæmia.

Arterial thrombosis is an important factor in the ætiology of *necrosis* and *gangrene*. Extensive disease may be present in the arteries of an extremity without seriously impairing its vitality, but the occurrence of thrombosis, either in the main artery or in its branches, is a common cause of failure of the local circulation, which terminates in gangrene. It must be pointed out, however, that thrombosis in a main artery will not result in gangrene, if the collateral circulation is normal; but if the thrombosis spreads into the collateral channels, or if these are obstructed by spasm or organic disease, then the vitality of the limb is immediately threatened.

The *diagnosis* and *treatment* of arterial thrombosis will be sufficiently dealt with in the articles on thrombo-angeitis (see page 4037), arteriosclerosis (see page 4043), and embolism (see below).

Arterial Embolism

The increasing success of the operation of embolectomy, which was first tried quite early in this century, has had the result of placing arterial embolism in the forefront of emergency surgery. The dramatic nature of its onset, the seriousness of its results, and the difference every hour makes to the success of surgical intervention, combine to invest the lesion with special interest to the adventurous mind of the modern surgeon. It is true that the opportunity to perform an embolectomy does not often come one's way, but it seems likely that more chances will occur when we convince physicians and general practitioners of the importance of timely diagnosis, and of the benefits of early operation.

Pulmonary embolism is not included in this article, as it has already received attention (see Vol. II, page 2165).

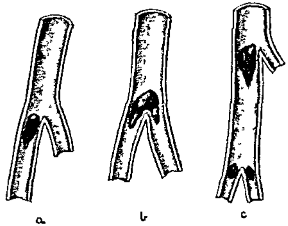
Pathology.

An embolus which lodges in an artery comes from the left side of the *heart* in more than 60 per cent of cases. Mostly it is a piece of organised blood clot detached from a diseased mitral valve, less often from a collection of ante-mortem clot in the left auricle. The heart may be the seat of malignant endocarditis, or of a simple endocarditis; auricular fibrillation not infrequently precedes the detachment of emboli. Occasionally the emboli come from septic foci in the lung, or from clot adhering to atheromatous ulcers in the aorta. In the rare cases of patent foramen ovale the emboli may be derived from the right side of the heart, or even from the systemic veins. Whatever their origin,

emboli are often multiple. A few months ago the writer saw a woman with embolism of the main arteries of all four limbs, with spontaneous recovery in one arm, Volkmann's ischæmic contracture in the other, and gangrene of both legs; the source of the emboli was a malignant endocarditis with marked fibrillation.

An embolus is carried by the blood stream until it reaches an arterial segment narrow enough to arrest its course. This site is usually one where a large or largish artery suddenly diminishes in size, and is frequently at or near a bifurcation; in the latter instance the embolus may not be quite large enough to obstruct the artery at once, but it may be arrested by saddling over the bifurcation, and subsequently completely block the artery by accretion of thrombosis. The most common sites of arrest, apart from the pulmonary artery, are the bifurcation of the common femoral, where the femoral pierces the adductor magnus, the

Fig 2197.—Mechanisms of embolic arrest.



bifurcation of the popliteal, and the bifurcation of the external iliac, the axillary artery where the subscapular branch is given off, and the bifurcation of the brachial. It must be noted that an embolus need not block an artery completely to cause total occlusion; the irritation produced by its presence excites a powerful vasoconstrictor reaction which converts a partial into a complete block for a sufficient period to enable secondary thrombosis to make it permanent.

The importance of *secondary* or *propagating thrombosis* following embolism is obvious. An embolus is associated with a much higher incidence of gangrene than a ligature of the vessel at the same point. In part this may be explained by coincident disease of the arterial tree, or by a depressed condition of the circulation as a whole, but unquestionably the chief reason is a peripheral spread of thrombosis down the artery and its branches, and particularly along the collaterals. Such a propagating thrombosis may completely occlude the territory of even

the most richly anastomosing artery, and not infrequently occurs with astonishing rapidity. Thus, some years ago the writer was able to show that the real cause of intestinal gangrene in embolism of the mesenteric arteries was not the embolus itself, but a secondary thrombosis propagated from it, and spreading widely and rapidly into the collateral vessels of the mesenteric arcades, as far as the vasa recta themselves (fig. 2198). This rapid spread of secondary thrombosis constitutes perhaps the strongest argument for prompt surgical intervention if the effects of arterial embolism are to be aborted. Fortunately, there appears to be an interval of a few hours before secondary thrombosis starts. Another factor deleterious to local vitality is a reflex vasoconstriction of the collateral vessels produced by sympathetic irritation

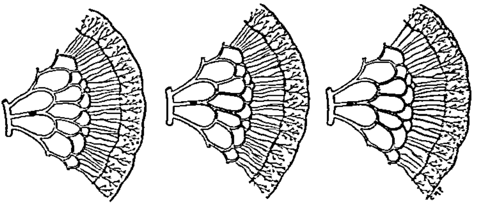


Fig. 2198.—Mesenteric embolism with propagating thrombosis.

of the arterial segment blocked by the embolus. According to Leriche this peripheral vasoconstriction seriously embarrasses the collateral circulation and may continue after embolectomy; to meet this danger, he suggests resection of the blocked segment of the artery (arteriectomy). This suggestion has recently been supported by Gosset, Bertrand and Patel.

Finally, it should be mentioned that small emboli may be detached from a main embolus in a proximal part of an artery, and move down to a lower level, or to one or more branches; such an occurrence may nullify the result of an embolectomy which removes the main embolus only. Furthermore, " showers " of minute emboli (e.g. from the lungs) may block a group of terminal vessels, and thus give a false clinical picture of main artery embolism.

Clinical Features.

It is important to remember that arterial embolism does not occur in a previously healthy patient. The majority are already suffering from obvious heart disease, many are seriously ill with malignant endocarditis, and some are in a state of auricular fibrillation. The discovery of a possible source for emboli is of great assistance in diagnosis.

The actual embolism is heralded by a sudden attack of very severe cramp-like *pain* in the affected limb. The pain is most marked along the course of the obstructed artery, but unfortunately it is always distal to the actual block, and is therefore not of much value in localising the exact site of embolism. The pain persists, although it may become less severe after a few hours. The pain is rapidly followed by *blanching*, most marked at the end of the limb, and increasing to a dead white pallor, and the patient may complain of *tingling* sensations. The pallid portion feels *cold* to the patient, and is actually cold to the touch. Quite soon *anæsthesia* occurs, producing a sensation of *numbness* to the patient, and this is accompanied by progressive *loss* of power, of muscular contraction, and of other functions. From the onset there is complete *loss of pulsation* in the arteries beyond the embolus, a sign of the greatest possible importance both in diagnosis and in localisation.

The *subsequent course* depends on the size of the vessel obstructed, and on the condition of the collateral vessels. The stage of intense pallor is usually followed by one of *patchy cyanosis*, which may or may not pass on to gangrene. *Gangrene* is much more likely to follow embolism of the lower limb than of the upper. With blockage of the brachial, and even of the axillary artery, there is more than a 50 per cent chance of recovery of the circulation without embolectomy; but, although gangrene may be averted, other ischæmic manifestations may result, such as permanent loss of power, wasting of muscles, and ischæmic contractures. In the lower limb, gangrene is extremely likely to result from embolism of the external iliac, common femoral, and upper part of the popliteal arteries, although the area which becomes gangrenous is usually considerably smaller than the total area supplied by the occluded artery. Embolism at the bifurcation of the popliteal artery or in the arteries of the leg is not likely to be followed by gangrene.

Diagnosis.

The diagnosis of arterial embolism is not difficult if its possibility is borne in mind. The sudden onset, the extremely severe and persistent pain, the loss of the pulse, followed rapidly by blanching, with sensations of tingling and numbness, constitute a very typical clinical picture, and when this occurs in a patient with a cardiac lesion,

especially a malignant endocarditis with fibrillation, there can be no room for doubt.

Many limbs can be saved by timely embolectomy, and an *early diagnosis* is therefore of the utmost importance. The brilliant results obtained by Swedish surgeons are largely due to the fact that physicians in that country are aware of the benefits of early operation, and are thus on the look-out for the occurrence of embolism. Similar results would be obtained in other countries if general practitioners were taught the importance of early diagnosis of embolism, and the benefits likely to be derived from timely surgical assistance. A good deal of suitable material might also be obtained if cardiac out-patients of hospitals were warned to report immediately symptoms and signs suggestive of embolism presented themselves.

Treatment.

The timely removal of an embolus from a large artery greatly increases the chance of survival of the limb, and therefore tends to prolong the life of the patient. It must be admitted that a large proportion of patients are already doomed by the concomitant cardiac lesion, but there is no reason why they should not be spared the horror of a gangrenous limb. Thus in 1933, Zierold published 11 cases of embolectomy, 9 of which were for lower limb emboli, with 8 recoveries of the circulation, but only 3 ultimate survivals of the patient.

Embolectomy was first successfully performed by Labey in 1911. In 1929, Key collected 216 cases, while in 1933, Danzis reviewed 129 cases in the literature between 1922 and 1932. All authorities agree on the importance of the *time factor.* Of 134 cases (reported by Key) in whom the operation was performed within 10 hours, 46 (34 per cent) were permanent cures, while 23 (17 per cent) died from the causative cardiac or vascular disease, but recovered their local circulation; this gives over 50 per cent of successful results from the embolectomy.

The earlier the operation, the better the outlook, for, with every hour that the embolus is left, progressive detrimental changes occur in the blocked part of the artery and in the vessels peripheral to it. Locally, the embolus becomes adherent to the arterial wall, in which degenerative processes and ulceration occur. The distal effects have already been mentioned, and are *vasoconstriction* and *propagating thrombosis.* The ideal time for operation is within *two or three hours* after the embolism, but up to six hours the outlook is definitely hopeful, as there is a delay of a few hours between the embolism and the occurrence of secondary changes in the artery and its branches. After twelve hours the prognosis is definitely poor, and after twenty-four hours the

operation is hardly worth doing, and gangrene is often already present; it should be mentioned, however, that Zierold reports two cases of successful result after 36 and 72 hours respectively.

Embolectomy is indicated with particular force in lower limb embolism, and in embolism of large arteries. It is unnecessary in blockage below the bifurcation of the brachial and popliteal arteries. In such cases, as well as in cases of high embolism which arrive too late for operation, the treatment has to be expectant (see section on Degenerative Arteritis, page 4043).

Localisation.

Apart from the avoidance of delay, *accurate localisation* of the site of embolism is the most important pre-operative factor of success. In most cases the embolus can be localised by a careful clinical examination, provided the clinician has a good knowledge of anatomy. The site of the *first pain* and the *upper limit of pallor* are of indirect value, inasmuch as they indicate that the embolism is at a higher level, but as the actual distance between the embolus and the ischæmic area is variable (depending mainly on the efficiency of the collateral circulation), the information obtained by this means is not sufficiently accurate. Of greater localising value is the examination of the arteries themselves, and particularly of their *pulse.* In an artery which is accessible to the fingers, e.g. the common femoral, axillary or brachial, one may be able to determine the exact point at which the pulse ceases, and sometimes even to feel the actual embolus as a longitudinal cord with a non-expansile transmitted pulsation. In deeper and, therefore, non-accessible arteries, information can still be obtained by examining the pulses, but it is less direct. Thus, if the pulse can be felt in the common femoral in Scarpa's triangle, but is absent in the popliteal, the probability is that the embolus blocks the bifurcation of the femoral.

When doubt still exists after a thorough clinical examination, localisation can be obtained by *arteriography*, but if this is not available the operation will be *exploratory* in the first place. The artery is exposed where there is most likelihood of the embolus being present; but if no embolus is found and the artery pulsates, a second incision is made lower down; when the artery does not pulsate and is empty, the second incision is made more proximally.

Arteriography.

By injecting a radio-opaque substance into an artery, it is possible by means of X-ray examination to localise an embolus with certainty. Arteriography has been employed in the investigation of cases of

arteriosclerosis, thrombo-angeitis, aneurysm, and arterio-venous fistula; it has also proved of some value in determining the condition of the collateral circulation in threatened gangrene from vascular disease.

The choice of a suitable and harmless radio-opaque solution has been a matter of considerable concern. Satisfactory visualisation of the arteries was first obtained by arterial injections of *sodium iodide* and *iodised oils*. Sodium iodide has proved too dangerous, as it damages the vessel wall and may cause gangrene: moreover it is painful and has been known to result in fatal poisoning. In 1930, Saito published 130 cases of successful injections with iodised oil, but this method is also dangerous owing to the possibility of oil embolism. The preparation in widest use to-day is *thorotrast*, a stable solution of *thorium dioxide*. It is injected on the X-ray table through an ordinary vein-puncture needle, under local anæsthesia; the artery proximal to the puncture is obliterated with a blood-pressure cuff, or the finger, as soon as it is certain that the needle is in the vessel, and 15 to 25 cc. of the solution injected. The skiagram is taken after three seconds, by which time the solution is distributed throughout the territory of the injected artery. In 1935, Veal and McFetridge reported on the results obtained by thorotrast injections in 200 cases; they claim that the solution is both painless and harmless, and that very valuable information can be obtained in cases of both threatened and actual gangrene, particularly in determining the best level for amputation. Thorotrast has also been widely employed in France, and in 1935 Leriche reported most favourably on it after extensive experience. The only drawback is that thorotrast is a mildly radio-active substance, and that it remains fixed in the tissues. Thus far no harmful consequences appear to have resulted, but the future will decide if any delayed effects occur.

(After Allen and Camp.)

Technique of Embolectomy (figs. 2200, 2201 and 2202).

Owing to the diseased condition of the cardio-vascular system, general anæsthesia must be avoided. *Local anæsthesia* should be preferred to spinal as the patient's sensations help in assessing the result of the operation. The blocked artery is exposed by a free incision, when it will be noticed that above the embolus the vessel is round and distended, with an expansile pulsation, while just below this part the firm mass of the embolus can be felt with ease. The wound is now flushed with sodium citrate solution, which is also used to moisten all instruments and swabs, and the adventitia round the blocked part of the

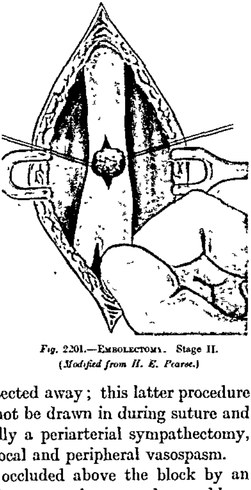

Fig. 2201.—Embolectomy. Stage II.
(*Modified from H. E. Pearse.*)

artery is picked up and carefully dissected away; this latter procedure assures that tags of adventitia will not be drawn in during suture and cause thrombosis; it is also virtually a periarterial sympathectomy, and may thus assist by abolishing local and peripheral vasospasm.

The artery is now temporarily occluded above the block by an assistant's fingers, or with non-crushing artery clamps, and opened by a longitudinal incision, preferably a little proximal to the clot. The embolus is then persuaded to extrude by gentle compression with the fingers, the artery being held open with fine traction sutures passed through its outer coats only. As soon as the block is removed some bleeding should occur from the distal end of the artery; if this does not

happen, then there are thrombi lower down, perhaps produced by propagating thrombosis. Such thrombi may occasionally be teased out with forceps, or removed by making a second incision in the artery some distance distally and irrigating the artery with citrate solution (fig. 2203).

As soon as blood starts to flow from the lower end of the artery, this is controlled by pressure or a clamp and the artery released proximal to the incision, and allowed to bleed for a moment, to wash out any proximal clot. The bleeding is then arrested again, and the artery and wound once more irrigated with citrate. The artery is now ready for suture, which is carried out along the lines indicated on page 4083.

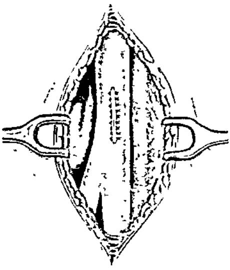

Fig. 2202—EMBOLECTOMY. Stage III. (*Modified from H. E. Pearse.*)

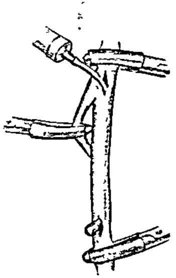

Fig. 2203.—PROCEDURE FOR REMOVAL OF DISTAL THROMBI.

If the exposed artery is empty, or completely solid with secondary thrombosis, whenever possible it should be exposed and opened by a second and more proximal incision. Where this cannot be done (e.g. the whole common femoral is empty or thrombosed), an attempt may be made to break up the embolus by passing a ureteric catheter up the artery, in the hope that a flow of blood will occur and wash it down. In embolism of the external or common iliac, the following procedure is sometimes successful: under spinal anæsthesia, the common femoral is opened below Poupart's ligament, while through an incision above the ligament the peritoneum is pushed out of the way, and the iliac vessel milked down in the hope of dislodging the clot.

Arteriectomy.

In 1933 Gosset and his associates, supported by Leriche, suggested that in certain cases extirpation of the thrombosed artery is

a more rational procedure than embolectomy. The advantages they allege are: (a) it is an easier operation, (b) there is no danger of damaging the intima and thus favouring subsequent thrombosis, and (c) it gives complete relief to the peripheral vasoconstriction, which is an important cause of inadequate collateral circulation. Other writers have recommended a *local arteriectomy*, limited to resection of the short segment of the artery in contact with the embolus, followed by end-to-end anastomosis (see page 4084). This has the advantage of removing the damaged part of the artery (where post-operative thrombosis is most likely to start), and at the same time of abolishing peripheral vasoconstriction, without depriving the limb of its main vessel or disturbing useful collateral arteries.

Vasospastic Diseases of Arteries

INTRODUCTION

In this section will be considered certain arterial conditions in which vasospasm plays a predominant part. The vasomotor control of blood-vessels is perhaps the main function of the sympathetic nervous system, although there is recent evidence that other factors enter into this control. Since the sympathetic system has been dealt with in a previous section of this work (see Vol. II, page 3099), it would be redundant here to embark upon a detailed discussion of the physiology of sympathetic activity, of methods of experimental and clinical investigation, or of the operations on the sympathetic devised to deal with vasospastic disorders. We shall, therefore, limit ourselves to a consideration of these disorders as *arterial* rather than as sympathetic lesions, and to a critical discussion of their surgical treatment, and of the results obtained therefrom.

The enormous interest attracted to the sympathetic system of recent years has somewhat obscured the fact that vasospastic disorders affect the arteries as well as their nerve supply. The experience of the past few years, however, is producing a more balanced outlook. Sympathectomy, even when wisely and widely performed, often gives only partial or temporarily complete relief, and sometimes leaves the patient no better, or perhaps even worse than before. For this and other reasons, attention is turning to other aspects of a problem which is proving more complicated than our early enthusiasm permitted us to think.

Of the essential nature of pathological vasospasm we know very

little. It can be produced by sympathetic stimulation of vasoconstrictor type; but it can also occur in a vessel which has been completely denervated, when it is either the result of a local tissue stimulus (e.g. cold), or of the action of " sympathomimetic " hormones reaching the arterial muscle via its blood supply. Why the abnormal sympathetic stimulation occurs, or why the local or blood-borne chemical stimulus takes place, is not clear. One thing, however, appears certain, and this is that vasospasm is not a separate entity, but occurs in numerous conditions, and is intimately associated with organic occlusive changes in the vessel walls. At present it would appear that the organic changes follow the functional spasm, and are caused by it, but the future may show that both are produced by the operation of a third factor, as yet unknown.

There are three common disorders of peripheral arteries, viz. degenerative diseases (arteriosclerosis, atheroma, etc.), thrombo-angeitis (Buerger's disease), and a large group of essential vasospastic conditions, of which Raynaud's disease is the most characteristic. At present we have no evidence that vasospasm plays any part in *arteriosclerosis* and allied forms of degenerative arthritis, but it is an important and possibly a causal factor in *Buerger's disease*, while in *Raynaud's* and similar disorders it is the predominant pathological event.

In this section will be considered only those conditions which are predominantly vasospastic. Raynaud's disease itself probably covers several distinct lesions, while allied to it are a number of more or less definite entities, such as *acrocyanosis*, *erythrocyanosis*, *hyperhydrosis*, and *erythromelalgia*. Vasospasm may also be a prominent feature in spinal cord lesions, especially *infantile paralysis*, in *cervical rib*, in *occlusion of large arteries*, and in *rheumatoid arthritis*.

A. Essential Arteriolar Vasospasm (Raynaud's Disease)

In the report of the Medical Research Council published in 1936 Lewis and Pickering, who have spent many years of study and research on disorders of the peripheral circulation, come to the conclusion that several distinct conditions are described under the heading of Raynaud's disease, and express the opinion that this term should be abandoned. Although we are bound to agree with this opinion, the name is too familiar to be dropped easily, but we propose to employ the alternative term " essential arteriolar vasospasm " and to limit it as far as possible to the class of case hitherto known as " typical " Raynaud's disease.

Pathology.

This condition is an *intermittent vasospasm* affecting the *digital arterioles* of the hands, and to a lesser extent the feet, without any occlusion of the larger arteries, and in its early stages without recognisable organic changes in, or permanent narrowing of, the peripheral vessels. The intensity of this *arteriolar spasm* was proved by Landis, who devised an ingenious method of measuring the capillary pressure in the nail-fold; writing in 1934, he states that under normal conditions the capillary pressure is about 40 mm., but during an attack of arteriolar spasm it may fall below 7 mm. As a result of this spasm certain colour changes occur in the fingers and toes, the physiology of which has recently been studied by Lewis and Landis. In the attacks of *blanching* (local syncope) the vasoconstriction is so intense that only a slight and intermittent leakage of blood occurs through the arterioles. During the earlier *cyanotic* attacks (local asphyxia) the spasm is less intense and more blood gets through the arterioles, while the actual colour (degree of cyanosis) depends on the stage of dissociation of oxyhæmoglobin into reduced hæmoglobin.

For a time Raynaud's disease apparently remains an *essential intermittent dysfunction*. But repeated attacks of arteriolar spasm in time lead to organic changes in the arterioles themselves, and also in the tissues they supply. The changes which occur in the digital arterioles are those of an *obliterating arteritis*. Cellular proliferation occurs in all the coats of the arterial wall, but particularly in the intima, and this is followed by fibrosis and structural occlusion. The picture is very similar to Buerger's disease, but only the smallest arteries and arterioles are affected. Until recently it was thought that these organic changes appear relatively late in the course of the disease, but we now know, on the authority of Lewis, that they often occur quite early. With the advent of structural changes Raynaud's disease passes from the stage of functional arteriolar spasm to that of organic occlusive arteritis. Although intermittent attacks of vasospasm still occur, subsequent vasodilatation becomes interfered with, and ultimately the vasodilator tests (see Vol. II, page 3172) may produce no appreciable increase of the blood-flow, showing that the arteriolar muscle has lost its ability to vasodilate. Among the structures affected at this stage are the *capillaries*. It has recently proved possible to microphotograph the capillaries of the nail-bed, using an oblique beam of light; in advanced Raynaud's disease they elongate, and become tortuous and dilated. The changes which occur in the skin and other tissues supplied by the vasospastic, and later fibrotic arterioles, are

given in the paragraph on complications; it may be stated at once, however, that the more serious and permanent changes, such as gangrene or scleroderma, are never the result of uncomplicated arteriolar spasm, but always depend on structural occlusion.

The actual *causation* of this condition of essential arteriolar vasospasm, or Raynaud's disease, is at present unsettled. Most writers still maintain that it is a *sympathetic neurosis*, resulting in abnormal activity of the vasoconstrictor nerves. This explanation was actually put forward by Raynaud as long ago as 1862, and there are several strong arguments in its favour. Among these are the high incidence of the disease in highly strung young women, the initiation of the attacks by emotional disturbance as well as by cold, the associated sudomotor activity, and the frequent, if temporary, relief of uncomplicated vasospasm given by sufficiently extensive sympathectomy. On the other hand, the failure to discover morbid changes in the sympathetic ganglia and other nerve centres leaves us without explanation of the origin of these vasoconstrictor impulses. Moreover, if the intermittent vasospasm is of nervous origin, why should it not involve other peripheral arteries or arterioles of the affected limbs?

In the last few years another view of the essential pathology of arteriolar vasospasm has been gaining ground. In 1929 Sir Thomas Lewis promulgated the theory that Raynaud's disease and allied forms of vasospasm are not due to disturbances of the sympathetic vasomotor control of vessels, *but to an increased susceptibility of the arteriolar* muscle itself to local stimuli, such as cold. This view is based on the experimental fact that strictly local vasospastic phenomena can be produced by local cooling and that these phenomena can be evoked after novocaine nerve block, and in sympathectomised patients. While this view and these findings have been questioned by J. C. White and others, there can be no doubt whatever that vascular tone and arteriolar spasm will return after a sympathectomy which has resulted in complete denervation of the vessels, and that such vascular tone and constrictor ability must be an essential property of the arteriolar muscle. In 1934 Smithwick, Freeman and White claimed that vasospasm after sympathectomy can be accounted for by the sensitivity of denervated arteriolar muscle to adrenalin, and that this sensitivity depends on degeneration of post-ganglionic sympathetic fibres. According to White, the reason for the much greater incidence of residual vasospasm after cervico-dorsal ganglionectomy, as compared with lumbar sympathectomy, is that in the former the degeneration of post-ganglionic fibres is almost complete, while in the latter sufficient remain

to protect the arteriolar muscle against the effect of circulating adrenalin. But more recently (1936) Grant has shown that the chemical substance is not necessarily adrenalin, but may be an adrenalin-like body, and that this does not come from the suprarenals or from the pituitary.

It seems reasonable to conclude that there are elements of truth in both hypotheses, and that the arteriolar muscle can be activated by sympathetic impulses, but also by chemical hormones in the circulating blood, or by chemical or physical changes excited and produced locally. Cannon has already shown that even the sympathetic does not act directly on plain muscle, but only through the intermediation of a chemical hormone, which he has called Sympathin E; this is said to be liberated between the nerve-endings and the arteriolar muscle as a result of vasoconstrictor impulses along the sympathetic nerves. Similarly, chemical bodies such as histamine, acetyl-choline, and a hormone christened the "H" substance, are now known to be responsible for vasodilatation. Adrenalin has long been known as an important vasoconstrictor hormone which circulates in the blood, but there is no reason why it should be the only one. In fact there is foundation for the belief that the adrenalin-like body recently described by Grant helps to maintain normal vascular tone, and that its concentration in the blood stream *may be a determining factor in the causation of excessive arteriolar constriction.*

By way of summarising these confusing facts, actual as well as hypothetical, the following theory is submitted of the pathogenesis of essential vasospasm. Normally, the tone of the arteriolar muscle, which is the controlling factor of vascular tone in general, depends on the action of chemical hormones, which are either brought to it via its blood supply, or manufactured locally. The degree of arteriolar tone is governed by the chemical nature of these hormones and by their degree of concentration. The circulating hormones may be of endocrine, myogenic or even neurogenic origin, while the local hormones are set free by sympathetic nerve impulses, or by local tissue changes excited by trauma, local cooling, etc. Some of these hormones are vasoconstrictor in action, others produce vasodilatation, and by balanced activity they are responsible for the maintenance of general vascular tone and of normal vascular reactions, for the conservation and loss of bodily heat, and for the adequate protection and blood supply of local tissues. We suggest that the essential cause of pathological vasospasm lies in an *inherent unbalanced sensitivity of the plain muscle of certain arterioles* to vasoconstrictor hormones, or alternatively that there is an inherent

tendency to the over-production of such hormones. We prefer the former explanation as it corresponds with the *local* distribution of pathological vasoconstriction. Admitting this arteriolar sensitivity, it is easy to see that attacks of pathological vasospasm may be excited by any factor which increases the supply of vasoconstrictor hormones. This factor may be a stimulus along the vasoconstrictor sympathetic nerves; it may be an increased concentration of adrenal, or pituitary, or other constrictor hormones in the blood; or it may be a strictly local accumulation of chemical hormones, produced by the action of cold or some other local stimulus. In normal people the increased production or supply of these vasoconstrictor hormones produces normal vasoconstriction, while in people with abnormally sensitive arteriolar muscle it causes pathological vasospasm.

This theory is submitted for what it is worth. At least it bridges over the main differences between the "sympathetic" and "local" schools, without conflicting with either. The removal of one source of supply of constrictor hormones (e.g. by sympathectomy) may abolish pathological vasospasm when the sensitivity of arteriolar muscle is only moderately increased; it may produce a temporary improvement even when the arteriolar sensitivity is markedly increased; but it cannot be expected to result in permanent cure, or even constant improvement, as the arteriolar sensitivity remains untouched, and the remaining sources of supply of vasoconstrictor hormones may soon compensate for the loss of one of them. We are thus able to account for the inconstant results of surgical denervation of the spastic arteries, and to harmonise the early improvement and subsequent relapse which are so commonly experienced after cervico-dorsal sympathectomies for Raynaud's disease. The higher incidence of prolonged relief after lumbar sympathectomy for vasospasm of the lower limbs may after all not be due to intact post-ganglionic neurones, but to a naturally lower level of increased sensitivity of the arteriolar muscle in this region, than in the more specialised and exposed extremities of the upper limbs.

Clinical Features and Course.

A mild tendency to arteriolar spasm is extremely common and is responsible for the "chilly" manifestations of otherwise healthy people who are said to have a "poor circulation." Their fingers become white or blue in cold weather, or after a few minutes in the sea, they are always warming their hands before the fire, and they are inordinately fond of hot-water bottles, bed-socks and thick gloves. Most of these people are women, and they are usually young and "highly strung." The phenomena they present are only an exaggeration of the normal vasocon-

strictor response to a cold stimulus, which is always most intense in the extremities. The attacks of vasoconstriction can be set into operation by stimuli other than cold, e.g. fear or intense emotion. Most of these "chilly" people lose their tendency to arteriolar spasm with the advent of middle age, but some show a progressive increase of vasoconstrictor tendencies, and in time become typical examples of Raynaud's disease. Considerable emphasis is laid by White on this sequence of events, and he states that the change over from the prodromal "chilly syndrome" to the fully fledged stage of Raynaud's disease sometimes follows intense emotional strain. Raynaud's disease may start at puberty, but is most commonly seen in the twenties. The worst cases begin young, while milder cases may not emerge from the prodromal stage until after thirty. More than nine-tenths of the cases are women, most of them of a neurotic or emotional disposition. Arteriolar spasm sometimes runs in families.

A typical established case complains of *intermittent attacks* of *symmetrical vasospasm* in the hands, and to a lesser extent the feet, with marked reduction of blood-flow in the digits. The attacks are brought on by cold, and occasionally by emotional disturbance. The arteriolar response to cold occurs below a certain *threshold of temperature*, which varies with the intensity of the disease, but is usually round about 60 degrees. At first, the attacks subside rapidly when the environmental temperature is raised above the critical threshold, e.g. going into a warm room or immersing the hands in warm water; but at a more advanced stage the vasodilator response is much slower, and may be incomplete.

The attack of arteriolar spasm is manifested clinically by sensations of *numbness*, followed by *tingling*, and by symmetrical *colour changes*, which are typically *phasic*. In a mild case the colour change may be limited to a *cyanosis* (local asphyxia), varying in tint from grey to purple, mostly affecting the fingers, and fading up the palm; similar changes affect the toes, but are characteristically milder. In advanced cases the colour changes are more definitely phasic, and the cyanosis is either preceded or followed by attacks of *blanching* (local syncope). This starts at the tips of the fingers, and spreads to their whole length, but does not involve the hand and is rarely seen in the toes; the colour reached at the height of the attack is dead white. It is probable that by the time attacks of complete local syncope occur there is some degree of structural occlusion. The *pulse is unaffected*, even in peripheral arteries such as the radial at the wrist, and the anterior and posterior tibial at the ankle. *Sweating* is a common and troublesome

symptom which may accompany the vasospastic attacks, but can also occur without them, and may even precede them for months. Particularly annoying are "attacks" of profuse hyperhydrosis brought on by emotion or excitement in young people, but these probably represent a clinical entity which is distinct from essential arteriolar spasm (see page 4036).

Further Course and Complications.

In mild cases the disease may show a spontaneous improvement with increasing age, or it may be cured by treatment or by removal to a warmer climate. But in more established cases the vasospastic attacks become more frequent and severe, occur at higher temperatures, and cause considerable disability, especially in cold weather. Moreover, further changes occur which might be classed as *complications*. Arteriolar spasm may affect the *nose*, *ears*, and even the *tongue*, while renal vasospasm occasionally occurs and causes an *intermittent hæmoglobinuria*. Vasoconstriction of the *retinal arteries* causes attacks of blurring of vision, while spasm of *cortical arteries* is occasionally responsible for transient hemiplegia or aphasia. Perhaps the most interesting complications are those which affect the *skin* of the digits. After repeated attacks of local syncope, patches of *anæmic ulceration* appear at the finger-tips. They heal in warm weather, but repeatedly break down, and after a while result in *dry gangrene*; this is usually quite superficial, but occasionally extends as far as the bone. By this time the disease is well past the stage of uncomplicated arteriolar vasospasm, and considerable structural changes are present in the arterial walls. In some cases the skin atrophies and becomes shiny, while the nails may show various degrees of *onychia*. At this stage the fingers become very susceptible to infection, and *paronychial whitlows* are common. In another and particularly severe type of the disease marked subcutaneous fibrosis occurs, with hardening and fixation of the skin to the underlying fascia (*scleroderma* and *sclerodactyly*).

Interesting changes also occur in the *bones* in chronic cases. The usual change is *decalcification* of the terminal phalanges, probably caused by reactionary hyperæmia following the syncopal attacks. In 1934, Watson Jones and Roberts drew attention to nodules of *calcification* which sometimes develop in and under the skin of the terminal phalanges and more proximally. They are mostly seen in conjunction with atrophic skin changes, and are doubtless caused by prolonged deficiency of the local blood supply owing to occlusive arteritis. It must be observed that there are reasons for believing that some of the above conditions are not actually stages in essential arteriolar

vasospasm (or "typical" Raynaud's disease), but represent allied vasospastic lesions as yet imperfectly differentiated from the main group.

Differential Diagnosis.

Apart from some of the complications, the above description applies to typical cases of Raynaud's disease. Many cases are encountered, however, which are *atypical*. The writer has seen a case in which vasospastic attacks with phasic colour changes occurred mostly on warm days, and another in which vasospasm was much more marked in the toes than in the fingers (this was not a case of thrombo-angeitis). Then there are patients who instead of having intermittent attacks suffer from more or less continuous vasospasm, while in others the arterial spasm is caused by some extra-vascular organic lesion, such as cervical rib, infantile paralysis, or rheumatoid arthritis. Although such cases differ from true Raynaud's disease, they resemble each other in so far as their circulatory disturbance is due to vasospasm. Of greater importance in the differential diagnosis are circulatory lesions caused by *organic arterial occlusion*. There are cases of arteriosclerosis and thrombo-angeitis which in some respects imitate Raynaud's disease, even to the extent of showing symmetrical colour changes in the hands and feet. The imitation, however, is never complete, and it is nearly always possible to discriminate between them. Organic arterial disease shows a different age and sex incidence; vasospastic phenomena, when they occur, are more rapid in their onset and do not last long; the peripheral pulse is weak or absent, or the arteries are obviously sclerosed, and calcification may be shown in skiagrams; muscular pain and actual claudication may occur. Any doubt left will usually be dispelled by the various vasodilator tests, although some difficulty may even then be found in distinguishing Buerger's disease or arteriosclerosis from late cases of vasospasm, with organic arterial changes.

Treatment.

The treatment of Raynaud's disease has always been unsatisfactory, and the surgical intervention so energetically pursued in the last five or six years has not done very much to improve it. Owing to the comparative failure of medical treatment, however, operative measures are justified if something more than transient relief can be expected of them, and if the course of the disease renders an attempt to arrest it desirable, even if such arrest proves partial.

Medical Treatment. The only really successful remedy is a change to a *warmer climate*, at least during the winter months. This will cure the

mild cases of intermittent spasm, with a low critical temperature threshold, whose circulation recovers completely between the attacks. For obvious reasons, this measure is only possible to wealthy patients, or to those who can find work in warm countries. Moreover, it will give only partial relief to more severe cases, with a high temperature threshold, and with commencing organic occlusion. Warm covering for the hands and feet in cold weather, and avoidance of unnecessary exposure and of emotional disturbances, are prophylactic measures suggested by common sense.

Physiotherapy, in the form of massage, radiant heat and diathermy, is of transient benefit, while *endocrine therapy*, and *X-ray treatment* to the sympathetic ganglia have been tried without much success. *Vasodilator drugs*, such as padutin and carnacton, are of little value in an intermittent condition. Definite temporary improvement, on the other hand, has been obtained with *fever therapy* (e.g. mixed typhoid vaccine at weekly intervals), with *dinitrophenol*, and with *typhoid H antigen*, all of which produce a marked dilatation of the arterioles, sufficiently prolonged to heal digital ulcers; but the first two are dangerous and unpleasant, and they all give only a short period of relief.

Operative Treatment. Before deciding whether or not to adopt operative treatment, several points must be given careful consideration: (1) Are the symptoms, or the degree of disability, sufficiently severe to justify an operation? (2) Is the disease progressive or stationary, or are there signs of improvement? (3) Do the vasodilator tests (see Vol. II, page 3173) indicate that the disorder is in the stage of functional arteriolar spasm, or do they show that organic occlusive changes are already present? (4) What exactly do we hope to obtain as the result of surgical intervention? (5) To what risk, if any, is the patient subjected by the operation?

We are certainly in a stronger position to-day than we were five years ago, inasmuch as the intensive surgical attack indulged in during this period has led to the accumulation of valuable knowledge based on experience. This knowledge enables us to select the cases most suitable for operation, to plan our operative procedures so as to give them the optimum chance of success, and to forecast the immediate and ultimate results which are likely to follow. In general, it may be stated that *operation is contra-indicated* in mild cases without serious disability, *and in cases which show a tendency to become stationary or to improve* spontaneously. Such patients should be kept under observation and be thoroughly re-examined every winter; vasodilator tests should be performed at regular intervals and complete records kept. In this way

we can determine whether the disease is improving, stationary, or progressive. Only when it is *progressive* should operation be considered, but if performed at all, it should be done at a relatively early stage, and while the disease is still mainly a functional vasospasm. We must also be quite certain that a *correct diagnosis* has been made, and that such conditions as cervical rib, myxœdema, thrombo-angeitis and arteriosclerosis, have been definitely excluded.

We thus arrive at the conclusion that operation should be considered in proved cases of uncomplicated arteriolar spasm in whom the disease is definitely progressive. The position is more difficult with regard to more advanced cases with commencing organic arteritis. Here the operation has a smaller chance of success; on the other hand, the disease is more troublesome, the disability greater, and the need for some relief more urgent. Our decision must be guided by the extent of disability present, and by the degree of vasodilatation which is still possible. When the vasodilator tests have shown that the vessels have lost their power to dilate, operation is obviously useless, but when *they still retain a reasonable proportion of their vasodilator power it* may yield real benefit, even if this be only in the direction of ameliorating complications.

The choice of *operative procedure* rests between periarterial sympathectomy, ramisectomy, and ganglionectomy. *Periarterial sympathectomy*, although still advocated by Leriche, has been largely abandoned. It is a very simple and harmless operation, but is only occasionally successful, and *then it gives only partial and temporary relief. Why it* yields even this transient benefit is a mystery, as the peripheral vasoconstrictor fibres travel along the somatic nerves and not along the main vessels. *Ramisectomy* was given a fair trial after the failure of periarterial sympathectomy. The operation consists of a division of the grey rami to the brachial plexus. Some successes followed its use, but these were usually either incomplete or temporary. The principles of ramisectomy are quite sound, but its technical difficulties are so great as to be almost insuperable. The rami are small, difficult to recognise, and have no constant plan in their arrangement; there may be several rami to each nerve and, unless every one is divided, partial failure is inevitable. Furthermore, the branch from the second thoracic ganglia to the brachial plexus was not known at the time that ramisectomy was in vogue. Even after a successful ramisection the vasospasm returns, usually after some months, probably owing to regeneration of the rami.

Cervico-dorsal ganglionectomy (see Vol. II, page 3190) is much the most

comfortable, and perhaps postpone organic changes and complications. On the other hand, in the more serious cases, in which the need for relief is greater, the ultimate result tends to be definitely unsatisfactory. The initial relief of spasm still occurs, and this may temporarily improve the patient's condition, and remedy troublesome complications, but eventual relapse is almost inevitable. Indeed, in some cases the patient's ultimate condition is worse than before the operation, chiefly because of the inability of the vessels to dilate when the environmental temperature is raised. Lewis and Pickering have proved the existence of vasodilator nerves in the sympathetic, by showing that sympathetic ganglionectomy destroys the power of peripheral arterioles to dilate as well as to vasoconstrict. It is undoubtedly this *loss of vasodilator reactions* that constitutes the chief drawback to sympathetic operations. Prior to operation the patient at least had the warm weather to look forward to, and could relieve vasospastic attacks by raising the environmental temperature; after it, even this temporary relief may be denied. We believe that serious consideration should be given to this possibility before operation is decided upon.

The remote results of *lumbar sympathectomy* for vasospasm of the lower limbs are much more satisfactory, and a large measure of prolonged relief may be confidently expected. Unfortunately, however, essential arteriolar spasm nearly always involves the upper limbs more than the lower, and it is small comfort to the patient to be cured of the lesser evil, while the greater ill remains unrelieved.

By way of conclusion, certain statistics may be quoted, which give an indication of the ultimate results of operation. In 1933, Gask reported seven cases of cervico-dorsal ganglionectomy for Raynaud's disease, most of which relapsed by the next winter. In 1935, White reported 26 cases of ganglionectomy for arteriolar spasm, many of them with complications suggesting organic changes. Twenty were cervico-dorsal sympathectomies, in ten of which the operation was thought to be incomplete, while six of them (60 per cent) resulted in failure. The other ten were complete resections of the stellate and second thoracic ganglia; in all the circulation of the hand, as shown by blood-flow measurements, remained poor; five were partial successes (50 per cent)

bright spot in the outlook of the surgery of vasospastic disorders. It should encourage further research until, as White states, a solution is found to our present difficulties with persistent vasospasm in the upper limbs.

B. Other Vasospastic Disorders

(1) *Acrocyanosis.*

This is a condition very closely allied to Raynaud's disease, and indeed generally regarded as a variety thereof. It is again an essential arteriolar spasm, and affects the most peripheral parts, especially the hands, nose and ears. Attacks of cyanosis occur in these exposed parts, but these attacks tend to be much more prolonged than in true Raynaud's disease; indeed, in some cases the hands are always cold and blue, except when the weather is very warm. With regard to *treatment*, there is nothing to add to what has been stated in the last section.

(2) *Erythrocyanosis.*

In a recent article (1936) Telford and Simmons give this abbreviated name to the condition hitherto called by the cumbersome title of *erythrocyanosis crurum puellarum frigidum.* It is a common disorder which affects young women and girls with stout and florid physique and large limbs, and consists of a reddish blue discolouration of the lower half of the calf. Males are very rarely affected.

Minor degrees of erythrocyanosis are extremely common but cause no disability. Occasionally, however, the disease becomes severe and may have very unpleasant consequences. In a typical advanced case, the lower half of the calf becomes purple and cold to the touch, while the circumference of the limb is increased by cellular infiltration of the subcutaneous tissue. The purple skin can be blanched by pressure, but the colour returns from all sides when the pressure is relaxed. The hair follicles shed their hair and enlarge, appearing as small red points on the purple skin. In some cases enormous hypertrophy of the subcutaneous tissue occurs, producing a thick cuff which projects just above the back of the ankle. The worst cases develop indurated nodules under the skin, which become painful and very tender, and may ulcerate; these ulcers may only heal in summer weather. Itching and burning sensations add to the patient's discomfort. The skin over the triceps may also be affected, but rarely to the same degree.

For some time the condition was thought to be tuberculous in origin, or to be an endocrine dysfunction, but there has never been any

comfortable, and perhaps postpone organic changes and complications. On the other hand, in the more serious cases, in which the need for relief is greater, the ultimate result tends to be definitely unsatisfactory. The initial relief of spasm still occurs, and this may temporarily improve the patient's condition, and remedy troublesome complications, but eventual relapse is almost inevitable. Indeed, in some cases the patient's ultimate condition is worse than before the operation, chiefly because of the inability of the vessels to dilate when the environmental temperature is raised. Lewis and Pickering have proved the existence of vasodilator nerves in the sympathetic, by showing that sympathetic ganglionectomy destroys the power of peripheral arterioles to dilate as well as to vasoconstrict. It is undoubtedly this *loss of vasodilator reactions* that constitutes the chief drawback to sympathetic operations. Prior to operation the patient at least had the warm weather to look forward to, and could relieve vasospastic attacks by raising the environmental temperature; after it, even this temporary relief may be denied. We believe that serious consideration should be given to this possibility before operation is decided upon.

The remote results of *lumbar sympathectomy* for vasospasm of the lower limbs are much more satisfactory, and a large measure of prolonged relief may be confidently expected. Unfortunately, however, essential arteriolar spasm nearly always involves the upper limbs more than the lower, and it is small comfort to the patient to be cured of the lesser evil, while the greater ill remains unrelieved.

By way of conclusion, certain statistics may be quoted, which give an indication of the ultimate results of operation. In 1933, Gask reported seven cases of cervico-dorsal ganglionectomy for Raynaud's disease, most of which relapsed by the next winter. In 1935, White reported 26 cases of ganglionectomy for arteriolar spasm, many of them with complications suggesting organic changes. Twenty were cervico-dorsal sympathectomies, in ten of which the operation was thought to be incomplete, while six of them (60 per cent) resulted in failure. The other ten were complete resections of the stellate and second thoracic ganglia: in all the circulation of the hand, as shown by blood-flow measurements, remained poor; five were partial successes (50 per cent) inasmuch as the mean temperature remained 5 to 10 degrees higher, and cyanosis and trophic troubles were prevented; the others continued to suffer from Raynaud's disease. Six operations were lumbar ganglionectomies, and they all gave excellent results, vasospasm being completely abolished and the skin temperature remaining 15 to 20 degrees higher than before. The success of the lumbar operation is the one

bright spot in the outlook of the surgery of vasospastic disorders. It should encourage further research until, as White states, a solution is found to our present difficulties with persistent vasospasm in the upper limbs.

B. Other Vasospastic Disorders

(1) *Acrocyanosis.*

This is a condition very closely allied to Raynaud's disease, and indeed generally regarded as a variety thereof. It is again an essential arteriolar spasm, and affects the most peripheral parts, especially the hands, nose and ears. Attacks of cyanosis occur in these exposed parts, but these attacks tend to be much more prolonged than in true Raynaud's disease; indeed, in some cases the hands are always cold and blue, except when the weather is very warm. With regard to *treatment,* there is nothing to add to what has been stated in the last section.

(2) *Erythrocyanosis.*

In a recent article (1936) Telford and Simmons give this abbreviated name to the condition hitherto called by the cumbersome title of *erythrocyanosis crurum puellarum frigidum.* It is a common disorder which affects young women and girls with stout and florid physique and large limbs, and consists of a reddish blue discolouration of the lower half of the calf. Males are very rarely affected.

Minor degrees of erythrocyanosis are extremely common but cause no disability. Occasionally, however, the disease becomes severe and may have very unpleasant consequences. In a typical advanced case, the lower half of the calf becomes purple and cold to the touch, while the circumference of the limb is increased by cellular infiltration of the subcutaneous tissue. The purple skin can be blanched by pressure, but the colour returns from all sides when the pressure is relaxed. The hair follicles shed their hair and enlarge, appearing as small red points on the purple skin. In some cases enormous hypertrophy of the subcutaneous tissue occurs, producing a thick cuff which projects just above the back of the ankle. The worst cases develop indurated nodules under the skin, which become painful and very tender, and may ulcerate; these ulcers may only heal in summer weather. Itching and burning sensations add to the patient's discomfort. The skin over the triceps may also be affected, but rarely to the same degree.

For some time the condition was thought to be tuberculous in origin, or to be an endocrine dysfunction, but there has never been any

evidence in favour of these views. Actually, it is very similar to the vascular lesions of severe infantile paralysis. The chief ætiological factor is undoubtedly a defective blood supply in a fatty area which is far out in the peripheral circulation. and which is exposed to the effect of cold owing to the feminine practice of leaving the lower limbs uncovered. There is probably a combination of arteriolar spasm with a deficient venous return, with the result that a harmful tissue product accumulates locally, which may be responsible for the reactive formation of nodules. Telford and Simmons suggest that the nodules of Bazin's disease, and of so-called traumatic fat necrosis, have a similar ætiology.

The *treatment* of mild cases consists mainly of warm covering and physiotherapy. For severe cases Telford and Simmons strongly recommend bilateral lumbar ganglionectomy. They publish ten cases, with excellent results from six months to four years after operation.

(3) *Hyperhydrosis.*

This is a distressing condition characterised by profuse sweating of the hands and feet, occurring in attacks. The patients are mostly young and highly strung individuals, and the attacks are generally brought on by emotional disturbances. Sympathetic dysfunction is undoubtedly responsible, and there may or may not be associated arteriolar spasm. The condition is an obvious handicap in certain occupations, as well as being a source of considerable worry and embarrassment.

Medical treatment is useless, and the only hope of cure lies in sympathetic denervation. This has been done both by ganglionectomy and by paravertebral alcohol injections into the sympathetic ganglia. The results of such operations have proved far more satisfactory than when performed for Raynaud's disease, as indeed would be expected from the unilateral sympathetic ætiology of hyperhydrosis.

(4) *Other Vasomotor Lesions.*

Sympathetic denervation has been tried in several conditions associated with disturbances of vasomotor control. Lumbar ganglionectomy has been performed for the chronic chilblains and cutaneous ulceration of the legs in *infantile paralysis, pyramidal tract lesions, spinal cord injuries*, etc.: the skin complications in these lesions are caused by defective blood supply with reduction of the arterial inflow and retardation of the venous return. There is also an associated vasoconstriction, as shown by the marked response to vasodilator tests. Such cases do extremely well after a lumbar ganglionectomy, although recurrence of the skin lesions ultimately occurs in a proportion of them.

Sympathectomy has also been performed on a large number of cases of *rheumatoid arthritis* with associated vasospasm. In selected cases, with a favourable vasomotor index (see Vol. II, page 3178), good results have been obtained; the circulation of the cold, clammy, and cyanotic limbs has been markedly improved, and some cases experienced considerable relief of pain, and even actual improvement of the arthritis.

Sympathetic surgery has also played a part in the treatment of *causalgia.* Since this condition is nearly always accompanied by marked vasomotor changes, it is safe to assume that there is coincident irritation of the sympathetic centres. Cases in which definite temporary relief is given by blocking the corresponding ganglia with novocaine should be treated by alcohol injection or ganglionectomy. Some success has also been claimed for periarterial sympathectomy.

Thrombo-angeitis Obliterans (Buerger's Disease)

It is curious that this important and far from rare disease escaped adequate recognition until Buerger gave it the above title and wrote a comprehensive monograph on it in 1924. He described it as a chronic occlusive disease of medium-sized arteries, especially in the lower limbs, almost limited to men, and showing a special predilection for Jews and for heavy cigarette smokers. Buerger also indicated that some cases show an associated thrombophlebitis, which may actually precede the occlusive arteritis. Since 1924 a great deal of work has been done on this disorder, and it is now recognised as a definite clinical and pathological entity, belonging to the vasospastic group of arterial diseases. Its outstanding features are severe claudication pain, colour changes, trophic troubles, and a marked tendency to gangrene.

Incidence.

The most striking feature of the disease is its limitation to men, who constitute 99 per cent of the victims. Although most patients are between 40 and 50 when they first come to us for treatment, they are usually by this time in an advanced stage of the disease, which probably starts in the middle thirties. Thrombo-angeitis affects the lower limbs and is nearly always bilateral, but the disease begins in one leg and then attacks the other; the upper limbs rarely share in the occlusive arteritis, although in some cases they show evidence of arteriolar spasm. The alleged preponderance of Jews has not been confirmed by

recent statistics, nor is there reliable evidence of other racial or class predilection, except that the disease often seems to attack men engaged in occupations involving exposure to inclement weather. Considerable difference of opinion has recently been expressed on the part played by *cigarette smoking*. The disease has been reported in non-smokers and it is very doubtful if tobacco ever acts as a direct cause. In a recent article (1935), however, Lampson has shown that during cigarette smoking there is a marked peripheral vasoconstriction, causing a fall in peripheral blood-flow and skin temperature, and an appreciable rise

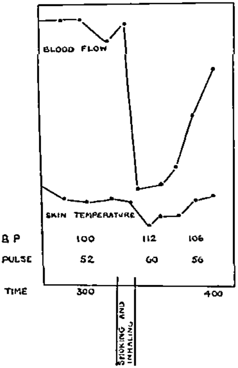

Fig. 2204.—Effect of cigarette smoking on peripheral circulation. (*After Lampson*)

of the blood-pressure and pulse (fig. 2204). This effect is increased by inhaling, and occurs both in normal people and in those with thrombo-angeitis, in whom it may cause sensations of coldness and pain. We conclude that inhaling cigarettes is an important contributory cause of thrombo-angeitis, and that it certainly does harm to patients already suffering from arterial disease.

Ætiology.

The actual causation of the disease is unknown. There is no evidence of blood changes, nor does syphilis or any other cause of arterial degeneration play any part. The one clear conclusion which emerges from recent research is that *arterial spasm* plays a definite part in ætiology.

It would appear that the disease starts as an intermittent vasospasm, that this spasm becomes more continuous, and that after a period, probably of some years, occlusive arteritis and thrombosis supervene. There are, therefore, broad similarities between thrombo-angeitis and Raynaud's disease, but the differences are even more striking, for while the latter attacks the upper limbs of young women, the former is almost limited to the lower limbs of middle-aged men. It almost seems as if there is some unknown factor which influences the effects of vasospasm according to the sex and the extremity involved. In this connection, it is of interest to observe that in the so-called epidemics of ergotism most of the patients are men and the lower limbs are more often affected. For the causation of the initial vasospasm there is no clear explanation. It is possible that continued exposure and tobacco may play some part, or that some cases may be toxic in origin, but it is more likely that these factors are predisposing rather than direct causes. There is certainly nothing to suggest sympathetic neurosis or excessive adrenal activity, and excised sympathetic ganglia show no pathological changes.

Morbid Anatomy.

Thrombo-angeitis mainly affects medium-sized arteries of the leg, e.g. anterior tibial, dorsalis pedis and posterior tibial. The disease attacks the arteries in a " patchy " manner, leaving lengths of normal vessel between the affected areas, but it nevertheless proceeds to complete arterial occlusion. The effects of such occlusion depend on the artery involved and on the condition of the collateral anastomotic channels. Serious results occur in occlusion of the upper part of the popliteal artery, where the anatomical provision for a collateral circulation is distinctly poor. The limb is also endangered by associated vasospasm of anastomotic branches, and later on by spread of the thrombotic process into the collateral vessels, or by a proximal extension into the femoral and iliac arteries. Fortunately, in most cases the disease remains localised to the medium-sized arteries, and the collaterals escape organic occlusion. Organic changes start in the *intima* which shows endothelial and sub-endothelial proliferation and becomes thickened and irregular. *Thrombosis* begins at the intimal irregularities; the clots are at first small and adherent to the arterial wall, but later the thrombosis spreads to uninvolved parts of the artery, where the clot lies free from the adjacent normal intima. The organic disease, therefore, starts as an obliterative endarteritis, the narrowed lumen becoming *completely occluded* by thrombosis. Later on, fibrosis occurs in the *media* and spreads through to the *adventitia*, and even to the perivascular tissues. By this time the thrombus has organised into

fibrous tissue, and it may show evidence of recanalisation. Although the disease is usually limited to the legs, occasionally it affects the upper limbs, and it has been reported in the coronary and mesenteric arteries.

The veins are affected in only a minority of cases, the condition being mainly a venous thrombosis with relatively little endophlebitis. Rarely, the *thrombophlebitis* precedes the arterial changes, and it is interesting to observe that it is sometimes of the *migrans* type.

Clinical Course.

The symptom that brings most patients to seek medical advice is *claudication*. This is a very intense cramping pain in the muscles of the calf and in the foot, which at first comes on after walking a considerable distance, and which is relieved by resting for a few minutes. Although the claudication starts in one leg, sooner or later it involves both. As the disease progresses, the pain comes on after walking shorter and shorter distances, and the patient is often pulled up quite suddenly by it. Walking rapidly or uphill brings on the claudication more quickly. Sooner or later, any muscular exercise causes pain and, worst of all, it begins to occur when the patient is at rest. This rest-pain is most severe in bed, but some relief is obtained by keeping the leg outside the bedclothes, and especially by hanging it over the edge of the bed.

On questioning the patient we may elicit the fact that attacks of coldness and blanching of the feet were noticed before the onset of claudication, and similar attacks may occur in the established stage of the disease. Occasionally these attacks are accompanied by sweating, and there can be no doubt that they are vasospastic in origin; they certainly support the view that thrombo-angeitis starts as a pure arterial spasm.

Some months or years after the onset of claudication, *postural colour changes* occur in the foot. At first the foot becomes discoloured only when it is hanging down; the colour is a dull red, starting in the toes and spreading up the dorsum. On elevation of the foot the red colour goes and gives place to a dead white blanching. The size of the angle of elevation required to produce blanching is known as the angle of circulatory efficiency, and is an index of the degree of arterial occlusion. The condition of the *pulse* in the palpable arteries is of great diagnostic importance. By the time claudication is well established, no pulsation can be felt in the dorsalis pedis or the posterior tibial, while in advanced cases the pulse is also lost or weakened in the popliteal and in the lower two-thirds of the femoral arteries. It is rarely lost in the femoral

artery above its bifurcation. In an excellent article published recently (1935), Telford and Stopford report cases in which the pulse in the tibial arteries was sometimes present and sometimes absent. The same phenomenon was observed in one case by the writer, and must be taken as strong evidence of intermittent arterial spasm. The thrombosed arteries can occasionally be felt as solid cords, largely owing to perivascular fibrosis.

Having reached this stage, the disease may remain stationary, and in some cases a *spontaneous improvement* sets in. This is partly attributable to opening up of collateral channels, but may be contributed to by recanalisation of the thrombosed arteries. In more than half the cases, however, the course unfortunately progresses downhill. *Trophic troubles* appear in the form of chronic onychia, with loss of nails, callous ulcers, and other skin changes. Finally, in about a quarter of the cases, black necrotic areas appear on the toes or heel, and spread more or less rapidly, usually as a *moist gangrene*, up the foot and leg. In the average case, several years elapse before this final stage is reached. Occasionally the course of the disease is *acute* and gangrene may come on in as little as three months. Telford and Stopford describe one case in which death occurred six months after the onset of claudication, from thrombosis spreading up the aorta and occluding the inferior mesenteric artery.

Thrombophlebitis appears in 10 to 15 per cent of cases, and is mostly of the migratory type (see page 4005).

Treatment.

Before undertaking treatment it is essential to exclude other types of arterial disease, particularly arteriosclerosis. The distinction from arteriosclerosis should not be difficult, as this affects people ten or more years older, is much more generalised in its distribution, and can be diagnosed by X-ray pictures. Having established the diagnosis of thromboangeitis, it is then wise to classify the case into one of two types—(1) with a good vasodilator response, and (2) with a poor vasodilator response. The simplest way of determining the *vasodilator power* of an ischæmic lower limb is with *spinal anæsthesia*. Cases associated with vasospasm, or in whom the collateral channels are capable of good vasodilatation, will respond well, showing a rise in their skin temperature of 10 to 15 degrees, as well as an improvement in colour and warmth. Such cases can be expected to derive real benefit from sympathetic denervation. When the vasodilator response is poor, however, it is obvious that little can be hoped for from operations on the sympathetic.

Medical treatment is mostly of temporary benefit, but since some of the cases tend to become stationary it is certainly worthy of trial.

Drugs by mouth are of no value, while injections of muscle extracts (e.g. lacarnol) or acetyl-choline only give very fleeting results. The fever treatment with mixed typhoid vaccine is also of temporary benefit, and the patient soon resents the repeated febrile reaction. Two conservative measures, tried recently, appear to give far more promising results. The first of these is the *Pavax* (passive vascular exercise) treatment described by Hermann and Reid in 1933. In this the leg is enclosed in a glass boot and subjected to alternately negative and positive pressure, the object being to encourage the development of the collateral circulation : reports of early results are definitely satisfactory. The other recent measure is intravenous administration of 5 per cent *hypertonic saline* solution in recently sterilised distilled water. This treatment was strongly recommended by Silbert in 1935, who published 524 cases with striking improvement; the injections are given twice to three times a week, starting with 150 cc. and continuing with 300 cc. The hypertonic saline is persevered with while improvement continues. Silbert also insists on the importance of *avoiding cigarette smoking*, which he considers the most important part of the treatment. Recent opinion strongly supports this contention.

Surgical treatment will be resorted to when medical measures fail to arrest the disease. All forms of *sympathetic operations* have been tried, but periarterial sympathectomy, ramisectomy, and adrenal denervation have failed to maintain the success originally claimed for them. Two operations, however, have shown a high proportion of good results in *selected cases*, namely, lumbar ganglionectomy and crushing of the peripheral nerves.

The chief advocates of *lumbar sympathectomy* for thrombo-angeitis are Telford and Stopford, in this country, and Adson and Brown, of the Mayo Clinic. In the article already referred to, Telford and Stopford give the results of 48 lumbar ganglionectomies, 42 of which were bilateral. They had no operation deaths, but six of their patients died subsequently, three of them from coronary disease. Of the remainder, 25 patients (nearly 60 per cent) were classed as good results (no rest-pains, walking well, and at work), 7 were fair results, and 10 (24 per cent) were failures. The best results were obtained in youngish patients with definite vasospasm. There can be no question that sympathectomy should be reserved primarily for cases which show a good vasodilator response after spinal anæsthesia, as these are the only ones in whom the collateral vessels have a chance to vasodilate. Adson and Brown state that only one out of every three patients admitted to the Mayo Clinic proved suitable for this operation. In other cases the

best that can be hoped for it is some relief from rest-pain, and perhaps a lower level of amputation when gangrene supervenes.

Crushing of the peripheral nerves is warmly advocated by White, whose experience with lumbar ganglionectomy has not been too happy; he considers that patients with thrombo-angeitis are not good risks for a major operation, and recommends this minor procedure as an alternative. At least two or three mixed nerves (the anterior tibial, musculo-cutaneous, and posterior tibial) are crushed with artery forceps through small incisions, about six inches above the ankle. This produces a motor, sensory and sympathetic paralysis of the foot, which lasts for three to six months. During this period as much vasodilatation is produced as in lumbar ganglionectomy, and this often proves sufficient to heal ulcers and to limit the spread of gangrene. Moreover, it gives much more complete relief from pain. After six months the nerves regenerate and the vasodilatation comes to an end, but the collateral circulation may have developed in the meantime sufficiently to produce some permanent improvement. In 1935 Smithwick and White reported 29 cases of nerve crushing with 17 cases of marked improvement. The temporary motor paralysis is of little consequence in the foot, but it prevents the application of this procedure to the upper limb. Whatever treatment is adopted a certain proportion of cases (15 to 25 per cent) terminate in gangrene, which necessitates *amputation*. Nerve crushing, lumbar sympathectomy, or the hypertonic saline treatment may limit the gangrene to the toes, and it may be possible to save most of the foot. But when the gangrene shows signs of spreading, or becomes associated with infection, a high amputation may be urgently indicated. As a rule, a below-knee amputation can be done with safety, but when severe spreading infection is present, or the circulation of the stump is doubtful, one should not hesitate to sever the limb through the thigh. Perhaps the most useful test to determine the proper level of amputation is the estimation of the skin temperature; of recent years *arteriography* has also proved of real value in this connection (see page 4017).

Degenerative Arteritis

(arteriosclerosis and endarteritis)

Ætiology.

Degeneration of the arteries (arteriosclerosis) is essentially a medical problem, but it has surgical aspects which require consideration. Although mostly seen in elderly people over 50, arteriosclerosis is not

necessarily a senile process and sometimes occurs in quite young people. Many factors enter into its ætiology, of which toxic states and metabolic disturbances appear to be the most important. Its association with syphilis, nephritis, heart disease, hypertension, diabetes and gout has long been known; it is also known to occur after acute infections, such as influenza and scarlet fever. Recent work, however, suggests that metabolic disturbances constitute an even more important ætiological factor. In diabetic cases arterial degeneration may occur quite early in life, and the present view is that excess of cholesterol in the blood is responsible for it. There are strong reasons for the belief that *disordered cholesterol metabolism* is also responsible for the arteriosclerosis of older people. The morbid changes in the arterial walls appear to be initiated by the accumulation of lipoid cells in the intima, and to a lesser extent in the elastic and muscular coats; necrotic and fibrotic processes follow. Evidence has been recently brought forward which shows that a diet with a high fat content promotes the early development of arteriosclerosis, while a mainly carbohydrate diet with low calorie value is likely to delay it.

Morbid Anatomy.

The morbid changes differ somewhat according to the location of the disease, of which there are two main types: In one, the changes mainly affect the *intima*, constituting a true *endarteritis*. There is a hyperplasia of the sub-endothelial layer, with a large accumulation of lipoid cells, and relatively little fibrosis. The hyperplasia tends to be *patchy* and, owing to poor blood supply, the lipoid patches undergo necrosis and constitute what is known as atheromatous plaques. Sooner or later the necrosis reaches the endothelium and the plaques become *ulcers*, which form the starting-point for *thrombus formation*. Old plaques which fail to ulcerate tend to calcify. This constitutes the type of arterial degeneration usually known as *atheroma*, and is mostly seen in large arteries of the elastic type, such as the aorta, innominate and iliac arteries. The weak areas left in the arterial wall may prove the starting-point of an aneurysm. Quite a different type of endarteritis affects small arteries, particularly those on which the collateral blood supply of a limb depends. Here the usual change is a marked sub-endothelial proliferation, passing on to fibrosis of the intima and media, and leading to marked narrowing and rigidity (obliterative endarteritis). These small vessels thus lose their ability to vasodilate when a special demand for such dilatation is made upon them by occlusion of main channels.

In the large muscular arteries of the limbs arteriosclerosis tends to

be more generalised, and the main changes occur in the *media* (mesarteritis). This becomes the site of a round-celled infiltration, which is followed by necrosis, fibrosis and *diffuse calcification*. The arteries are converted into rigid tubes, with calcareous material deposited in thick rings, but there is not the same tendency to endothelial ulceration and thrombosis as in the intimal type. This type of arteriosclerosis has been termed the Mönckeberg sclerosis, and appears to be associated with hypertension and cardio-vascular strain. The two varieties, however, not infrequently coexist.

Of special surgical interest are the morbid changes which involve the *arteries of the lower limbs* in cases of *arteriosclerotic gangrene*. Marked fibrous thickening occurs in the intima, narrowing the lumen, and spreads to the media and adventitia, while extensive calcification occurs between the intima and media. Fatty degeneration follows, and necrotic patches develop under the endothelium. When the endothelium itself is reached, thrombosis occurs and causes complete occlusion of the vessel (fig. 2205). In diabetes the same changes occur, but at an earlier age. The *smaller branches* of these arteries show intimal thickening, hyaline degeneration, and fibrosis, with marked narrowing, and ultimately obliteration of the lumen. This is the explanation of the poor collateral circulation in lower limb arteriosclerosis, and therefore of the narrow limit of safety which exists between the occurrence of total occlusion of the main artery (e.g. by supervening thrombosis or embolism) and the onset of *gangrene*. In thrombo-angeitis, in diabetic arteritis of young people, and in many cases of arterial embolism, the collateral vessels are frequently unaffected, and there is thus a much wider range of safety between occlusion of a main artery and gangrene.

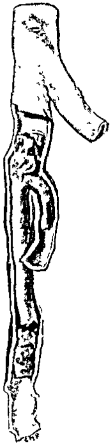

Fig 2205.—ARTERIOSCLEROSIS AND THROMBOSIS OF FEMORAL ARTERY. (*Museum, Royal College of Surgeons.*)

Clinical Course.

The course of arteriosclerosis is generally very slow. The manifestations of greatest surgical interest are those which depend on impairment of the circulation in the lower limbs. The nutrition of the skin, muscles and bones suffers, leading to atrophic changes, while the relative ischæmia causes rapid fatigue, aching pains on walking, paræsthesia,

and intolerance to cold. True intermittent claudication also occurs, but is neither as common nor as severe as in thrombo-angeitis. Cramping pains at night are more frequent and may cause insomnia. The pulses may be feeble and the hardened arteries are usually palpable.

The development of actual *gangrene* is often preceded by signs of increasing arterial occlusion, such as colour changes and marked coldness of the feet, and is sometimes determined by an attack of thrombosis in the narrowed arteries. The direct cause of the gangrene may be trivial, e.g. slight trauma, or a mild local infection, which in a limb with an adequate blood supply would be easily dealt with. The course of the gangrene varies. If the main vessels are not completely occluded, or if the smaller collateral arteries are not seriously affected, the gangrene may remain localised to a superficial patch, or at most it may involve one or two toes. But if either extensive occlusion of the main arteries, or advanced obliteration of the collaterals be present, the gangrene is likely to spread. Infection, by lowering local resistance, by producing a local reaction, and by exciting thrombosis, is another important cause of extension of the gangrene.

Diagnosis.

When one is confronted with a threatening of actual vascular gangrene of the lower limb it is important to ascertain the cause. Vasodilator tests will show whether the vascular lesion is vasospastic or organic: complete failure to elicit a response suggests arteriosclerosis, for even in advanced thrombo-angeitis some vasodilatation is frequently obtainable. The reader must be reminded, however, that occasionally cases of arteriosclerosis are associated with some vasospasm (see page 4029). The diagnosis from thrombo-angeitis has already been considered, but it may be repeated that definite evidence of calcification of the arteries can be obtained by X-ray examination. The histamine wheal test is of special value in the prognosis of arterial occlusion, particularly in diabetic cases: with a good reaction there is no danger of gangrene, but with a negative response gangrene is threatening and special precautions must be taken to prevent it.

Treatment.

From a surgical point of view the treatment of arteriosclerosis resolves itself into two guiding principles: (1) *to prevent gangrene* when this is threatening; and (2) *to treat gangrene* when it has begun. All other aspects of treatment belong to the physician.

In carrying out the first principle, Reid states that every effort must be made to save an affected limb during a critical period, because

a circulatory balance may eventually be established, and gangrene can often be avoided by simple therapeutic measures. Abstinence from fatty food, and treatment of a constitutional cause are of obvious importance. The patient must wear warm and comfortable shoes and stockings, and avoid exposure to cold or damp. Walking must be carefully regulated, and abrasions and other injuries to the feet avoided, while even the most trifling local lesion, such as corns, callosities and ingrowing toe-nails should be treated with the greatest caution. The greatest possible cleanliness and asepsis must be observed. When the local circulation is obviously failing, rest in a horizontal position is essential, the legs being kept at the level of greatest circulatory efficiency. Every attempt should be made to open out the collateral circulation with dry heat, contrast baths, and possibly the Pavæx treatment (see page 4042). A constant temperature foot-cradle devised by Starr and maintaining a temperature of about 35° C. has proved very useful in the treatment of both threatening and actual gangrene. Vasodilator drugs are useless, while the fever therapy with typhoid vaccine is dangerous, as it may start a thrombosis.

Attempts to improve the circulation in an arteriosclerotic limb by operation have, on the whole, proved unsuccessful. *Ligature of the femoral vein* has been of some value in moderate arteriosclerosis with local areas of defective supply, provided the peripheral pulse is still present. It acts by balancing the distribution of the available blood supply to the leg, and occasionally seems to avert threatening gangrene. *Operations on the sympathetic* are of no real value in arteriosclerotic ischæmia, although by producing temporary vasodilatation of collateral vessels they may save an odd case of gangrene here and there. *Periarterial alcohol injections* and *peripheral nerve block* are subject to exactly the same criticism.

When gangrene has actually started, the above conservative measures must be continued with even greater application, in the hope of localising the process. Every care must be taken to keep the gangrene dry and aseptic, and amputation should be withheld until a line of demarcation has formed, unless there is evidence of spreading infection, massive gangrene, or exhausting pain. When an *amputation* has been decided upon, the level at which it is performed is of the greatest importance. For small areas of necrosis with a good line of demarcation the surgeon need only assist nature by dividing a tendon or disarticulating a toe-joint; the resulting wound may already be partly healed, or it may only heal after long delay and repeated breaking down. But when the gangrene is spreading, when infection has occurred, and particularly

when the dorsalis pedis and posterior tibial arteries are not pulsating, a high amputation is essential. Estimation of the skin temperature, and the regional response to the histamine wheal test, may help to determine the proper level of the amputation. But in general one has to choose between a below-knee amputation, which has a low immediate mortality but a greater chance of necrosis in the stump, and a thigh amputation, with its higher immediate death-rate but better prospect of healing.

In recent years, *arteriography* has proved of considerable assistance in determining the best level of amputation for vascular gangrene. By its use accurate visualisation of the main and collateral arteries has been made possible, and the information thus obtained is of obvious importance. For further details and technique the reader is referred to page 4017.

CHAPTER IV

Aneurysms

CLASSIFICATION

The *term aneurysm is derived from a Greek word which means* dilatation or widening. Its strict pathological meaning is a local dilatation of a blood-vessel, producing either a regular enlargement of the whole lumen (*fusiform aneurysm*), or an irregular enlargement of one side (*saccular aneurysm*). Local dilatation may involve an artery, a vein, or both. A *venous aneurysm* (see fig. 2206) is very rarely encountered as a strictly local lesion, although aneurysmal dilatations are often seen as cyst-like swellings of a varicose vein. *Arterio-venous aneurysms* constitute a fairly common condition, to which a great deal of surgical interest has been attracted in recent years (see page 4072). Unless otherwise specified, however, the term aneurysm is used to designate an *arterial lesion*.

A distinction must be made between a *true aneurysm*, and what has come to be known as a *false aneurysm*. The former is produced by a fusiform or saccular expansion of an artery, and the walls of the aneurysm are thus, at least in part, derived from the walls of the parent vessel. A false aneurysm, on the other hand, is not a dilatation of an artery, but a circumscribed fibrous-walled hæmatoma, produced as the result of extravasation from a wounded or ruptured artery, and preserving its communication with this vessel.

Classification.

An *arterial aneurysm* may be congenital or acquired. *Congenital arterial aneurysms* are extremely rare; they are associated with abnormalities in the development of the vascular walls, and have been described at the base of the brain, in the splenic artery, the internal carotid artery, and elsewhere. Intra-cranial congenital aneurysms are occasionally responsible for fatal subdural hæmorrhage in young people, without trauma or vascular disease (see under Intra-cranial Aneurysms, page 4070).

Acquired aneurysms are conveniently classified into: (1) Spontaneous or idiopathic; (2) traumatic; (3) embolic (mycotic); and (4) erosion aneurysm.

Embolic and erosion aneurysms are of little surgical importance, as neither their course nor their consequences can be influenced by surgical intervention (except in occasional instances). *Embolic* or *mycotic aneurysms* result from the arrest of septic emboli in an artery, with consequent infection of the arterial wall, which softens and gives way, even under normal conditions of blood-pressure. They are usually multiple, are caused by infective endocarditis, are mostly seen in children, and proceed rapidly to fatal rupture.

Erosion aneurysms may be produced by any erosive lesion which

Fig. 23[illegible].—[illegible] aneurysm. (*Museum, St. Mary's Hospital.*)

weakens or destroys the tissues surrounding and supporting an artery, and which invades the arterial walls themselves. The best example is provided by an artery which is left isolated in a tuberculous cavity in the lung: such a weakened and unsupported vessel gradually gives way to the pressure of its blood, dilates to form an aneurysm, and finally ruptures, perhaps causing fatal hæmorrhage. A similar process may affect an artery left stranded in the midst of an acute infective lesion or of a destructive malignant growth. The writer has seen an acute aneurysm develop in a common femoral artery traversing a large abscess, following an infected gunshot wound of the thigh, with compound fracture of the femur; amputation through the hip had to be

resorted to, after all other measures for the control of repeated and alarming secondary hæmorrhage had failed. Another erosion aneurysm of a large artery seen by the writer involved the common carotid, in a case of extensive sloughing of the neck from secondary carcinomatous ulceration; sudden rupture of the aneurysm proved a merciful ending.

Spontaneous and *traumatic aneurysms* are by far the most important varieties from the surgical point of view, and will take up the greater part of this section.

Apart from arterial aneurysms, two other varieties are of surgical importance, viz. *arterio-venous aneuryms* and *cirsoid aneurysms*, both of which will receive adequate consideration.

Idiopathic (Spontaneous) Aneurysms

Ætiology.

Aneurysm is about ten times more common in men than in women. More than 50 per cent of cases occur between the ages of forty and fifty-five. The most common predisposing cause of spontaneous aneurysm is *syphilis*.

The lesion appears to be more common in temperate climates, and among Anglo-Saxon races, but in America there is a high incidence among negroes, probably owing to the prevalence of syphilis in this race. Occupations entailing cardio-vascular strain, especially intermittent increase in blood-pressure (e.g. heavy lifting), and also work associated with repeated trauma of a main artery, are ætiological factors of some importance. It is undoubtedly the exposure to vascular and other forms of trauma which accounts for the much higher incidence of aneurysms in the male sex.

A true aneurysm rarely occurs in a vessel which was previously healthy. The preservation of the arterial calibre, and its resistance to vascular stresses, depends on the muscular and elastic tissues of the *media*. Any condition which interferes with the nutrition and well-being of the media deprives the arterial wall of its resistance to internal pressure, and must thus be regarded as predisposing to the development of an aneurysm. It is because syphilis mostly involves the middle coat of large arteries that it forms such an important ætiological factor. By causing an obliterative endarteritis of the vasa vasorum, and by a direct "toxic" action on the muscle cells and elastic elements, syphilis produces a degeneration of the media. The degenerated tissue is replaced by a connective tissue *proliferation*, and the resistant muscular

and elastic wall becomes an unresponsive and rigid fibrous covering, which can no longer efficiently control variations in the arterial pressure, and is liable gradually to give way before maximal variations.

Syphilis is not the only disease that can produce degenerative changes in the media (*mesarteritis*). Other infective lesions, chronic alcoholism, gout, and some forms of arteriosclerosis are occasionally responsible. Mesarteritis is, of course, a diffuse condition, and when an aneurysm follows it tends, at least in its early stages, to be *fusiform* in shape. The reason why the dilatation of the artery is localised, and not diffuse, probably depends on local effects of vascular strain or external trauma, as well as on the unequal distribution of the more intense degenerative changes.

Apart from diffuse medial fibrosis, syphilis, arteriosclerosis and other infective or degenerative conditions produce changes in the *intima* of large vessels (*endarteritis*), which may also play a part in the causation of aneurysms. Such intimal changes tend to be more localised in their distribution, and are best seen in cases of *atheroma* of the aorta. Local patches of intimal necrosis occur, which sometimes affect part of the underlying media, and the resulting weak spot in the arterial wall may be the starting-point of an aneurysm. Aneurysms formed under such conditions are usually of the *saccular* type, although a so-called *dissecting aneurysm* also develops in the same way.

Trauma undoubtedly plays an important and direct part in the ætiology of true aneurysms. Mostly the trauma is *internal, or vascular*, and is produced by intermittent and marked increases of arterial blood-pressure, such as accompany severe occupational strain, or unaccustomed exertion in elderly men of sedentary habit. Vascular trauma may act with special force on certain points, such as arterial bends (e.g. aortic arch), or where large short arteries undergo a sudden and marked diminution in calibre (e.g. innominate, or common carotid).

External, or rather *extra-arterial trauma*, is a less common ætiological factor of true aneurysms. Such trauma may be repeated, e.g. bending or stretching of an artery during strenuous games and exercise; or it may be single, as in cases where an aneurysm develops at the site of a previous fracture or dislocation. A true aneurysm may also start from a scar in the wall of an artery, which is the result of an old injury.

Morbid Anatomy.

An aneurysm consists of a sac, which communicates with at least one but usually several vessels, and of contents. It is customary to classify sacs into *fusiform*, *saccular*, and *dissecting* (fig. 2207). In the

last type a cleavage occurs through the media, part of which remains in the wall of the artery, while the rest is pushed away with the adventitia by the accumulation of blood in the line of cleavage, to form the sac of the aneurysm. Dissecting aneurysms usually start from an atheromatous ulcer, and are therefore mostly seen in the thoracic or abdominal aorta.

True *fusiform aneurysms,* in which the whole wall of the artery is evenly expanded into a regularly ovoid dilatation, are rarely seen. Aneurysms of large deep-seated arteries, such as the aorta, are often fusiform at first, but subsequently one side yields more than the other, and the aneurysm becomes increasingly sacculated. In a true fusiform aneurysm all the coats of the artery are represented. Thus, it is usually

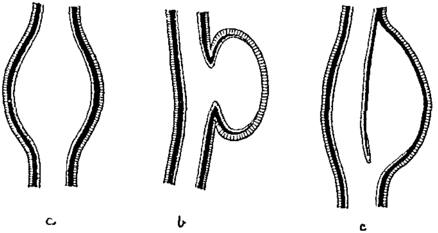

Fig. 2207.—Types of Aneurysm *a.* Fusiform. *b.* Saccular. *c.* Dissecting.

entirely lined by the intima, although this may be irregular and atheromatous in patches. The media is stretched and atrophied, but muscular and elastic tissues are recognisable, particularly near the junctions of the aneurysm with its parent artery. The adventitia becomes much thickened by a peri-aneurysmal fibrosis. Figure 2208 provides a good example of an aneurysm which started as the fusiform variety, but which now shows all the characters of the saccular type.

A large majority of aneurysms are *saccular.* As already mentioned, aneurysms of the large internal vessels may be fusiform at first, but become saccular later. Aneurysms in the limbs are nearly always saccular from the start, largely because trauma plays a dominating influence in their causation. The wall of a saccular aneurysm is profoundly different from the wall of its parent vessel. Although it is true that it may have an endothelial lining, and that the endothelium may regenerate from the parent vessel even after it has been destroyed, the other layers show marked alterations. It may be possible to trace

Treatment.

Since ancient times the treatment of aneurysm has proved of immense interest to both physicians and surgeons. *Medical treatment* has rarely been able to do more than relieve symptoms, and occasionally retard the enlargement of the aneurysm. *Prophylactic treatment*, however, particularly the early and thorough eradication of *syphilis*, is of the utmost value, and is largely responsible for the recent diminution in the incidence of the lesion. Other important preventative measures are: treatment of any general vascular disease, particularly hypertension, and avoidance of undue or unaccustomed strain by predisposed persons.

Most medical methods aim at increasing the coagulability of the blood in the aneurysm, and thus favouring thrombosis. Perhaps the oldest is the starvation treatment advocated by Hippocrates. This has been combined with absolute rest in bed, drugs such as potassium iodide or calcium, intramuscular injections of 2 per cent sterilised gelatin, and repeated bleedings. Real improvement has so rarely attended these remedies that they should be reserved for cases in which no surgical measures can be considered.

Surgical treatment, although rationally employed as far back as the second century by Antyllus, was sadly hampered until asepsis, anæsthesia, and the other great discoveries of modern times, gave surgeons the chance to solve what is essentially a surgical problem. That this solution has been only partly successful is due not to any lack of interest or skill, but to the peculiar difficulties presented by the anatomical situation of aneurysms, which are usually placed astride some vital part of the vascular apparatus.

Surgical measures may be conveniently divided into mechanical and operative, both of which are applied either directly to the aneurysm, or indirectly to its artery.

Mechanical Procedures. These include compression, acupuncture, and the introduction of foreign bodies into the aneurysm.

Compression was a favourite measure in pre-antiseptic days. Its object was to encourage thrombosis and consolidation of the aneurysm, and also to improve the collateral circulation. Direct compression of the aneurysm proved painful and dangerous, but indirect compression of the supplying artery enjoyed a great vogue. Either the fingers or clamps were employed, the compression being applied intermittently. The writer recalls being one of a relay of dressers who, under the supervision of an elderly surgeon, ineffectually squeezed upon the femoral artery, day after day, for a popliteal aneurysm. In these days the only

indication for compression is to increase the collateral circulation, prior to an open operation.

Acupuncture was used by Macewen for inoperable aneurysms, but never became popular. Needles were inserted into the aneurysm in such a way that the blood current made them scratch the opposite intima. It was hoped that this would cause an endarteritis, which might favour clot formation.

Insertion of foreign bodies, such as wire, horse-hair, etc., was employed by Moore, D'Arcy Power and others, with the object of stimulating thrombosis. In a modification of this method, a powerful current is passed through a coil of wire introduced into the aneurysm, which is said to "sear" the intima and so initiate an obliterating arteritis. Inserted wire may also be employed for electrolytic treatment, which is known to cause clotting. Although these methods appear somewhat fanciful, there can be no doubt that they have a limited field of application, especially in aneurysms of the thoracic aorta which can be reached between the ribs by an anterior approach. Satisfactory results have been obtained, and as recently as 1935 Thompson, Souttar and Howells reported a case of aortic aneurysm greatly improved for three years by the insertion of Colt's wire umbrella through a special cannula, the clinical improvement being confirmed radiographically.

Operative Treatment. The operative treatment of aneurysms resolves itself into four main procedures: ligature, aneurysmotomy, excision, and aneurysmorrhaphy. Another operation, brought forward in recent years, is decompression of the sac by arterio-venous anastomosis.

(1) *Ligature* of the artery aims at obliteration of the aneurysm by promoting clotting. Although of great historical interest, its indications in these days are strictly limited. All possible arterial sites and all kinds of ligature material have been employed. The ligature may be applied immediately proximal to the sac (Anel's method), or with the intervention of a branch (Hunter); it may be applied just distal to the aneurysm (Brasdor), or again beyond one or more branches (Wardrop); finally, the artery may be ligated both proximal and distal to the sac (Pasquin).

Although one or other of the above ligature procedures is included in most modern operations, when applied alone they often fail to obliterate the aneurysm, and they rarely insure against recurrence. Failures and relapses are due to *revascular… of the sac by collateral branches.* Inclusion of such collaterals … ·tion endangers the vitality of the limb. Moreover, the … hind and continues to exert harmful pressure effects, … may be displaced into new collaterals and so … For these reasons

Treatment.

Since ancient times the treatment of aneurysm has proved of immense interest to both physicians and surgeons. *Medical treatment* has rarely been able to do more than relieve symptoms, and occasionally retard the enlargement of the aneurysm. *Prophylactic treatment*, however, particularly the early and thorough eradication of *syphilis*, is of the utmost value, and is largely responsible for the recent diminution in the incidence of the lesion. Other important preventative measures are: treatment of any general vascular disease, particularly hypertension, and avoidance of undue or unaccustomed strain by predisposed persons.

Most medical methods aim at increasing the coagulability of the blood in the aneurysm, and thus favouring thrombosis. Perhaps the oldest is the starvation treatment advocated by Hippocrates. This has been combined with absolute rest in bed, drugs such as potassium iodide or calcium, intramuscular injections of 2 per cent sterilised gelatin, and repeated bleedings. Real improvement has so rarely attended these remedies that they should be reserved for cases in which no surgical measures can be considered.

Surgical treatment, although rationally employed as far back as the second century by Antyllus, was sadly hampered until asepsis, anæsthesia, and the other great discoveries of modern times, gave surgeons the chance to solve what is essentially a surgical problem. That this solution has been only partly successful is due not to any lack of interest or skill, but to the peculiar difficulties presented by the anatomical situation of aneurysms, which are usually placed astride some vital part of the vascular apparatus.

Surgical measures may be conveniently divided into mechanical and operative, both of which are applied either directly to the aneurysm, or indirectly to its artery.

Mechanical Procedures. These include compression, acupuncture, and the introduction of foreign bodies into the aneurysm.

Compression was a favourite measure in pre-antiseptic days. Its object was to encourage thrombosis and consolidation of the aneurysm, and also to improve the collateral circulation. Direct compression of the aneurysm proved painful and dangerous, but indirect compression of the supplying artery enjoyed a great vogue. Either the fingers or clamps were employed, the compression being applied intermittently. The writer recalls being one of a relay of dressers who, under the supervision of an elderly surgeon, ineffectually squeezed upon the femoral artery, day after day, for a popliteal aneurysm. In these days the only

indication for compression is to increase the collateral circulation, prior to an open operation.

Acupuncture was used by Macewen for inoperable aneurysms, but never became popular. Needles were inserted into the aneurysm in such a way that the blood current made them scratch the opposite intima. It was hoped that this would cause an endarteritis, which might favour clot formation.

Insertion of foreign bodies, such as wire, horse-hair, etc., was employed by Moore, D'Arcy Power and others, with the object of stimulating thrombosis. In a modification of this method, a powerful current is passed through a coil of wire introduced into the aneurysm, which is said to "sear" the intima and so initiate an obliterating arteritis. Inserted wire may also be employed for electrolytic treatment, which is known to cause clotting. Although these methods appear somewhat fanciful, there can be no doubt that they have a limited field of application, especially in aneurysms of the thoracic aorta which can be reached between the ribs by an anterior approach. Satisfactory results have been obtained, and as recently as 1935 Thompson, Souttar and Howells reported a case of aortic aneurysm greatly improved for three years by the insertion of Colt's wire umbrella through a special cannula, the clinical improvement being confirmed radiographically.

Operative Treatment. The operative treatment of aneurysms resolves itself into four main procedures: ligature, aneurysmotomy, excision, and aneurysmorrhaphy. Another operation, brought forward in recent years, is decompression of the sac by arterio-venous anastomosis.

(1) *Ligature* of the artery aims at obliteration of the aneurysm by promoting clotting. Although of great historical interest, its indications in these days are strictly limited. All possible arterial sites and all kinds of ligature material have been employed. The ligature may be applied immediately proximal to the sac (Anel's method), or with the intervention of a branch (Hunter); it may be applied just distal to the aneurysm (Brasdor), or again beyond one or more branches (Wardrop); finally, the artery may be ligated both proximal and distal to the sac (Pasquin).

Although one or other of the above ligature procedures is included in most modern operations, when applied alone they often fail to obliterate the aneurysm, and they rarely insure against recurrence. Failures and relapses are due to revascularisation of the sac by collateral branches. Inclusion of such collaterals in the operation endangers the vitality of the limb. Moreover, the tumour is left behind and continues to exert harmful pressure effects, while the clot in the sac may be displaced into new collaterals and so render them ineffective. For these reasons

simple ligature often fails to arrest the growth of an aneurysm, and is indeed associated with an actual risk of post-operative gangrene.

(2) *Aneurysmotomy*, in which, after ligature of the main vessels and of the collaterals entering the aneurysm, the sac is incised and evacuated, is a better operation, provided the ligatures are inserted close to the sac. It removes one cause of pressure—the clot, ensures against persistence or recurrence of the aneurysm, and also prevents embolism and thrombosis of collaterals. This operation was first described by Antyllus in the second century, and was recommended 70 years ago by Symes, who modified the procedure by obliterating the openings of the parent vessel from inside the aneurysm. After evacuation, the sac may be pleated, packed, or filled with a muscle graft.

(3) *Excision* of the aneurysm, after near-by ligature of all the vessels communicating with it, is unquestionably the best operative procedure. It produces a permanent cure and removes all relievable pressure effects. Unfortunately it is only applicable to a minority of aneurysms, i.e. those which are accessible, and can be freed from surrounding structures without inflicting such damage as will more than neutralise the benefits of removing the aneurysm.

When excision of the sac can be combined with reconstruction of the main artery, it becomes an ideal operation. But the cases on which this can be done are very few, and the reconstructed artery, which, of course, must be quite healthy, may not remain patent for more than a short period. Of necessity, such reconstruction is usually an end-to-end anastomosis (see page 4084), but in small saccular aneurysms (mostly traumatic) the removal of the sac may leave a one-sided wound of the artery, which can be repaired by lateral suture.

(4) *Aneurysmorrhaphy* was first described by Matas in 1902. Its great advantage is that the operation is performed entirely from within the sac, without disturbing collateral vessels and other extra-saccular structures. It is virtually an eradication of the aneurysm, and in the hands of the originator and his disciples has proved easier and safer than excision of the sac; furthermore, its range of application is somewhat wider than that of excision, although it is still mostly limited to peripheral aneurysms. Whilst it is true that the method has not proved equally successful when tried by other surgeons, it remains a brilliant achievement of conservative surgery.

Endo-aneurysmorrhaphy, to give it its full title, is of three types—*obliterative*, *restorative*, and *reconstructive*. In all types it involves temporary arrest of the blood stream by compression of the main artery proximal to the sac. This may be done by tourniquet, lengths

of wide tape, or artery clamps (see page 4083). The restorative and reconstructive operations can only be performed when the walls approximate to those of a healthy normal artery, and are rarely applicable to other than traumatic aneurysms. In the great majority of spontaneous aneurysms the walls are too degenerated to allow of any but the obliterative operation.

Technique of Endo-aneurysmorrhaphy.

(*a*) *Obliterative* (fig. 2209). One side of the sac is exposed and incised, and the contents emptied. The openings of the parent artery, and of other communicating vessels, are sutured from within. Finally, the sac is obliterated with layers of invaginating sutures.

(*b*) *Restorative* (fig. 2210). This operation is limited to saccular aneurysms with one opening into the parent artery. This opening is

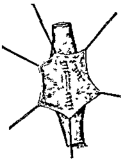

Fig 2209.—Obliterative endo aneurysmorrhaphy.

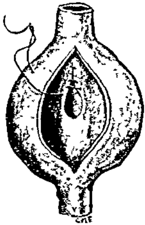

Fig 2210.—Restorative endo aneurysmorrhaphy.

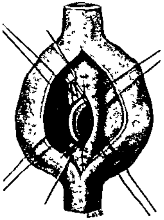

Fig. 2211.—Reconstructive endo aneurysmorrhaphy.

sutured, after incision and evacuation of the sac, again from within, but without narrowing the restored artery. The sac itself is obliterated as before, and at the same time used to strengthen the arterial suture.

(*c*) *Reconstructive* (fig. 2211). This procedure is rarely applicable, being reserved for aneurysms, originally fusiform, in which the two openings of the parent artery are close together, and the wall sufficiently healthy to justify an attempt to reconstruct the artery. A rubber tube is inserted into the two openings of the parent vessel, and a connecting channel is made between them by suturing the adjacent parts of the sac over the tube, which is removed just before the completion of the suture. The rest of the sac is dealt with as before.

Although the restorative operation sometimes succeeds in its object, the reconstructive procedure cannot be expected to do more than provide a temporary arterial channel. In time the reconstructed

artery becomes gradually occluded, but a valuable interval may be obtained for the establishment of an adequate collateral circulation.

(5) *Arterio-venous Anastomosis* (fig. 2212). In 1932, Babcock published an ingenious procedure, which is said to decompress the aneurysm by producing a large arterio-venous anastomosis in its vicinity. It is a hydro-dynamic fact that pressure exerted on the walls of a tube is diminished by increasing the velocity of a fluid running through it. On this principle, Babcock recommends for aortic aneurysm an

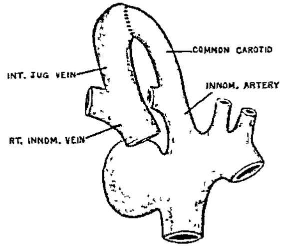

Fig 2212.—Babcock's operation of carotid jugular anastomosis for aortic aneurysm

anastomosis of the cardiac ends of the common carotid artery and internal jugular vein, the distal ends of both vessels being ligatured. This has the object of creating a by-pass, which relieves the pressure of an expanding aneurysm by accelerating the flow of blood through it. Up to 1932 this operation had been performed some 50 times, and it is claimed that pressure symptoms, especially pain, have been relieved, and that the danger of increasing growth and rupture has been lessened. Babcock suggests that the operation might be attempted for aneurysms in other situations.

Traumatic Arterial Aneurysms

In the section on arterial injuries (see page 4007) it was stated that both penetrating wounds and subcutaneous ruptures of an artery are followed by a local extravasation of blood, with the development of an *arterial*

hæmatoma. When the injured artery is large, the wound or rupture extensive, and the surrounding tissues loose and plentiful (e.g. in the axilla, groin or thigh), a very large amount of blood may be extravasated rapidly. The result is a *diffuse pulsating hæmatoma,* quickly growing to a huge size, and producing acute or even fatal anæmia. At first, a penetrating wound of an artery may communicate with the surface, and there may be brisk arterial bleeding. But after a while this ceases owing to shifting of overlying planes, clotting, or suture of the wound. Jagged incomplete ruptures, such as sometimes complicate fractures, and partial transverse wounds often bleed more than longitudinal wounds or complete ruptures.

A rapidly enlarging arterial hæmatoma is in no sense an aneurysm, but it is if anything more serious. The extravasation of blood, apart from endangering life, exerts severe pressure on surrounding structures, and by obliterating the injured artery and collateral vessels it may destroy the vitality of the limb. Associated œdema and a marked inflammatory reaction over the hæmatoma often lead to a mistaken diagnosis of cellulitis or abscess.

When the wound or rupture of the artery is smaller, or the surrounding tissues are firm and closely arranged, extravasation of blood is checked and can only proceed slowly. The result is a circumscribed pulsating tumour, which develops a definite wall of thick connective tissue and laminated clot, and which differs from a true aneurysm only in the fact that the sac is not derived from the walls of the artery, but from a condensation of surrounding fibrous tissue. This is a *false* or *traumatic aneurysm,* and represents a clinical entity of surgical importance, very common in war-time, but also not infrequently encountered in civil life.

Such traumatic aneurysms occur mostly in the arteries of the limbs, since these are particularly liable to injury. The writer has seen them in the common femoral, the profunda femoris, the femoral in Hunter's canal, the popliteal, the brachial, and the radial at the wrist. In civil life, injuries with broken glass (especially in the wrist and forearm), stab wounds, fractures and dislocations, and violent attempts at reduction of these, are the most common causes.

From the point of view of *diagnosis,* a circumscribed traumatic aneurysm presents the same clinical picture as a spontaneous aneurysm, except that the patient is often younger, and the cardio-vascular system is healthy. The history of trauma and the frequent presence of a scar over the swelling facilitate diagnosis. In any case this is rarely difficult, as the aneurysm usually develops in an accessible situation.

Two further points require mention: A circumscribed traumatic aneurysm may start as a diffuse arterial hæmatoma, in which extravasation becomes arrested and the more distal blood clot is absorbed; the area near the injured artery is ultimately walled off by a fibrous capsule, which forms the sac of the aneurysm. The other point is that a traumatic aneurysm may not start to develop until weeks or months after the arterial injury. In these cases the wound of the artery closes after a negligible extravasation, but a weak scar forms, and this yields to some vascular strain at a subsequent period, with the gradual or rapid formation of a traumatic aneurysm.

Treatment.

The treatment of a traumatic aneurysm is essentially operative. The patients are usually young and healthy, and the injured vessel is often quite free from degenerative changes, and so lends itself to restorative operations. There has been considerable difference of opinion as to the optimum time for operation. In the Great War, German surgeons adopted early operative intervention, but French and British surgeons on the whole favoured delayed interference.

Actually the time for operation and the procedure employed will depend on circumstances, which vary with each case. Among these are: (1) *The rate and amount of blood extravasation.* When this is sufficient to endanger life, operation must be undertaken without delay. (2) *The condition of the collateral circulation.* A rapidly enlarging hæmatoma may so obstruct the collaterals as to threaten gangrene, and this danger can only be overcome by early intervention. On the other hand, a circumscribing traumatic aneurysm tends to be associated with gradual improvement in the collateral circulation, which may constitute a reason for delay. (3) *The presence of infection.* This should postpone any attempt to deal with the aneurysm, unless the surgeon's hand is forced by the threat of secondary hæmorrhage. (4) *The condition of the sac and surrounding tissues.* In the first day or two an arterial injury is easy to repair, but after a few days the tissues become infiltrated with fluid and cellular exudate, and are too friable to permit of suture. At the end of some weeks, however, the aneurysm becomes circumscribed, and the surrounding tissues firmer, while the arterial walls are less friable and easier to suture. We can thus conclude that the optimum time for operation is either very soon after the injury, or after a delay of some weeks.

There is no standard operative procedure for traumatic aneurysm, and *surgical technique* can only be discussed in a general way. The first necessity is temporary control of the blood-flow, which is obtained by

one of the methods given on page 4083. Absolute asepsis and a thorough exposure are equally necessary. The reader is referred to the section on arterial ligature (see page 4085) for a description of the best methods of approach to various arteries. The actual operative procedure will depend on the size of the artery, the nature of the injury, the time of the operation, and the changes in surrounding tissues.

Early operation will be mostly needed for wounds or ruptures of large arteries. As there has not been time for the collateral circulation to open out, every effort should be made to restore the main channel. The incision must be made to give good exposure to the injured artery, and need not necessarily be over the hæmatoma. After blood and clots are washed away, the arterial injury is examined and, if possible, repaired (see page 4085). Clean incised wounds are easier to suture than lacerated ones, particularly if they are longitudinal in direction. Complete division or rupture of an artery may be repaired by end-to-end anastomosis, but only when this can be effected without tension. All dead spaces should be obliterated, and the incision closed without drainage.

When the injured artery is unimportant there is, of course, no necessity to repair it. If completely divided, the two ends should be ligatured or closed by suture. A partial division should be completed between ligatures, so that the ends can retract.

Late operation will usually encounter a definite and circumscribed traumatic aneurysm. The treatment of this differs from the treatment of a spontaneous aneurysm only in so far as it more frequently lends itself to restorative procedures. The repair of the injured artery may be undertaken either from within the sac, or outside it ; but it is obvious that the sac itself, being completely non-arterial, must not be used in reconstructing the artery, except perhaps by reinforcing the arterial suture. When the artery has been repaired, the sac is either excised or obliterated by sutures ; the second is the better alternative as it does not entail injury to surrounding structures. Aneurysms of small arteries, however, are best treated by aneurysmotomy or excision, after all communicating vessels have been ligated.

When an injured large artery cannot be repaired, it should be treated by complete division between strong ligatures. In such cases the question of simultaneous ligation of its accompanying vein should be seriously considered (see page 4086).

Surgical Treatment of Special Aneurysms

AORTIC ANEURYSM

Attempts at radical attack are almost invariably fatal, and although sometimes described as heroic, they are not rational procedures. These attempts include proximal ligature, distal ligature, and aneurysmorrhaphy.

There are three minor or indirect surgical procedures which give a fair prospect of temporary relief:

(1) *Paravertebral injections of alcohol* into the upper thoracic sympathetic ganglia, after preliminary novocaine block, can be expected to give complete relief when the aneurysm causes severe pain. In 1935, White reported three cases of painful aortic aneurysm treated in this manner, with complete and prolonged relief.

(2) *Insertion of wire* through a cannula, with or without galvanic or electrolytic currents, has been discussed already (see page 4059), and is worthy of trial when the aneurysm reaches the anterior thoracic wall. Several cases have been greatly benefited by this procedure.

(3) *Arterio-venous anastomosis* (see page 4062) seems to hold out the greatest prospect of real relief. It is based on a sound principle and has already given some striking results.

ANEURYSM OF INNOMINATE ARTERY

Exposure of the innominate artery (see Vol. II, page 1948) is not too formidable a procedure for the modern surgeon, who will not hesitate to remove part of the clavicle and sternum; but treatment by proximal ligature is only occasionally possible, as the aneurysmal dilatation usually involves the adjacent part of the aortic arch. Figure 2213 shows a case where such ligature was performed, but the aneurysm is obviously an early one. The treatment usually recommended is distal ligature of its two branches, i.e. the common carotid and subclavian. To have any real chance of success, the ligature of these vessels must be done simultaneously and as close to the aneurysm as possible. Not infrequently, however, the proximal parts of these arteries are distended by the aneurysmal process, and the ligatures have to be applied beyond an important collateral, such as the vertebral artery. When the carotid and subclavian are ligated near their origin there is serious danger of cerebral complications and of gangrene of the arm; while with any form of ligature, Babcock has shown that the pressure on the walls of

the aneurysm (and thus its rate of enlargement) is increased owing to slowing down of the blood current. For these reasons it seems probable that the best treatment for an innominate aneurysm is an *arterio-venous anastomosis* between the cardiac ends of the common carotid artery and internal jugular vein (see page 4062).

CAROTID ANEURYSM

For some unknown reasons aneurysms of the *common carotid artery* (see also Vol. II, page 1942) are almost as common in women as in men. The most frequent site is near the bifurcation, and pressure symptoms are usually prominent. The problems of treatment are complicated by the danger of *cerebral damage* after sudden

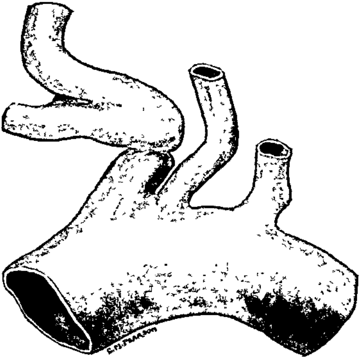

Fig 2213.—Aneurysm of the innominate artery. (*Museum, Royal College of Surgeons*)

complete occlusion of the common carotid, whether by ligature or other procedure. The incidence of cerebral complications has been said to be as much as 25 per cent or more, but it appears to be considerably less than it once was. In young people it is usually quite safe to ligate the artery above and below the aneurysm, which is then excised or obliterated. In patients of over 40, however, it is safer to employ *gradual occlusion* of the artery. This can be done with Halsted's metal bands, or with fascial strips which are tightened in stages. Bell and Tillotson recommend that this gradual occlusion be done distal to the sac, if possible ; it is certainly true that proximal ligature may fail in its object, as it permits reflux of the blood down the external

carotid to reach the internal. This, incidentally, may result in embolism of the latter. If the common carotid *must* be ligated below the aneurysm, the external carotid should be tied as well.

Gradual distal occlusion may result in a cure. If this does not materialise, the collateral circulation beyond the aneurysm may improve sufficiently to allow of a radical operation later. Perhaps the best radical procedure in these cases is *obliterative endo-aneurysmorrhaphy.*

Aneurysms of the extra-cranial part of the *internal carotid* are difficult to treat, particularly the erosion aneurysms which sometimes complicate tonsillar infection, and which are apt to be diagnosed and incised as abscesses. They are very difficult to approach for direct attack, and probably the best method of treating them is by ligature of the common and external carotid arteries. In 1926, Winslow collected 88 cases of internal carotid aneurysm, 43 of which were spontaneous, 18 erosive, and 26 traumatic.

External carotid aneurysms are easily reached and can be dealt with by excision.

SUBCLAVIAN ANEURYSM

This is almost limited to men, and occurs on the right side much more often than on the left; both facts suggest that strain may be an important causal factor. The treatment presents special problems, the most important of which are the anatomical position of the artery, behind the clavicle and very close to the pleura and brachial nerves, and *the danger of gangrene of the arm following sudden occlusion of the artery.*

Although quite recently Elliot advised *proximal ligature,* followed if necessary by distal ligature, with or without excision of the sac, many surgeons would reserve this for cases in which the efficiency of the collateral circulation has been proved by previous compression of the artery. When the aneurysm involves the first part of the right subclavian Elliot recommends *ligature of the innominate,* after resection of the inner end of the clavicle and the adjacent part of the sternum. If temporary compression of the artery shows a deficient circulation, however, a restorative aneurysmorrhaphy is indicated. (See also Vol. II, page 1951.)

AXILLARY ANEURYSM

Aneurysms in the axilla involve the distal two-thirds of the axillary artery, and the upper part of the brachial (fig. 2214), or some of their main branches. They are almost all traumatic in origin, and they tend to enlarge rapidly and to compress the axillary vein and brachial plexus.

Owing to the immediate proximity of important structures, excision of axillary aneurysms is both difficult and dangerous. Ligature,

whether proximal or distal, or both, is associated with a very real risk of gangrene. For these reasons the intra-saccular procedures of Matas are particularly indicated in this situation. Restorative or reconstructive *endo-aneurysmorrhaphy* is the method of choice in definitely circumscribed aneurysms, while the obliterative operation will have to be done if these are impossible. For an imperfectly circumscribed traumatic aneurysm, the sac should be incised, and the wound of the artery repaired by lateral suture.

ILIAC ANEURYSMS

Aneurysms of the common and internal iliac arteries are very rare, but the external iliac artery is not an uncommon site (see fig. 2208). Diagnosis is not made until the swelling has grown to a considerable size. The simplest treatment is distal ligation, i.e of the common

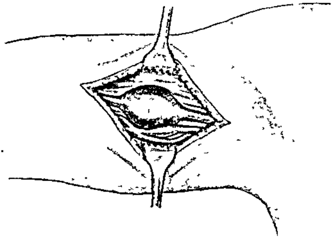

Fig 2214 —TRAUMATIC ANEURYSM OF THE BRACHIAL ARTERY, WITH ACCOMPANYING THROMBOSIS OF THE BASILIC VEINS
(*After Hubert A Royster*)

femoral, but this should not be attempted as it is very likely to lead to gangrene. Proximal ligature is difficult, and is best done with a strip of fascia. Sometimes obliterative aneurysmorrhaphy can be performed successfully, and is undoubtedly indicated whenever possible.

FEMORAL ANEURYSM

Ligature of the common femoral artery is too dangerous to the vitality of the limb to be permissible nowadays. Aneurysms of the common or superficial femoral are mainly traumatic in origin, and are therefore particularly suitable for restorative procedures. Sometimes it is possible to resect the aneurysm and to restore the artery by lateral or end-to-end suture. In other cases a restorative endo-aneurysmorrhaphy may be done. But even if an intra-saccular obliteration proves necessary, this is less dangerous than ligature. For all these procedures satisfactory hæmostasis is provided by temporary proximal occlusion of the artery with a length of tape.

hæmorrhage (see also page 5481). The patient often survives the first hæmorrhage, but recurrences are likely, and any of them may prove fatal. Rarely, the aneurysm does not rupture into the subarachnoid space, but leaks or ruptures into the cerebrum.

Pre-rupture diagnosis is essentially in the province of the neurologist, and can only be discussed briefly here (see also page 5481). The suggestive clinical features are: (1) Recurring migraine-like headaches; (2) involvement of cranial nerves, especially III, IV and VI; (3) loss of visual acuity; (4) pain in the distribution of the trigeminal nerve; and (5) occasionally, symptoms of VII or VIII nerve involvement, and of cerebellar involvement. Various combinations of these symptoms occur, most of them may be absent, and they may all be occasioned by other intra-cranial conditions. Pre-rupture diagnosis is thus extremely difficult, and is only occasionally made. In rare cases auscultation of the skull with a stethoscope reveals a bruit.

Of recent years *radiological* examination has provided much-needed assistance. A stereoscopic X-ray examination of the skull may show a rounded shadow near the brain base. Very recently *cerebral arteriography* (see also page 5483) has been attempted on a large scale by Moniz of Lisbon, and this promises to be of real value in the diagnosis of intra-cranial aneurysms; by this method about 10 cc. of thorotrast is injected into the common or internal carotid, after the artery has been exposed under local anæsthesia.

The diagnosis of *subarachnoid hæmorrhage* is not difficult, and when it occurs spontaneously it is strongly indicative of ruptured intra-cranial aneurysm. Often after a sudden strain, or exposure to strong sunlight, the patient is suddenly seized with violent pain in the occipital region and back of the neck. The pain becomes excruciating, and is soon followed by nausea and vomiting. The patient gradually loses consciousness, but may not do so completely, and passes into a state of cerebral irritation and stupor. The temperature rises to 102 degrees or more, and there is photophobia and marked restlessness. Rigidity of the back of the neck is a common and important sign, but deep tenderness in the nape of the neck is even more constant. Kernig's sign is also generally positive.

The symptoms and signs are obviously those of *meningeal irritation*, and many so-called cases of sunstroke in this country are doubtless examples of ruptured aneurysm. The diagnosis is definitely confirmed by *lumbar puncture*, which yields a deeply blood-stained fluid.

Surgical Treatment.

The treatment of spontaneous subarachnoid hæmorrhage has so

POPLITEAL ANEURYSM

This is much the most common site for peripheral aneurysms. It is only rarely caused by obvious trauma, and yet trauma of some obscure kind is probably often responsible. The aneurysm may be in the upper part of the popliteal space, or low down between the gastrocnemii; in the latter situation it is very liable to lead to gangrene, owing to pressure on important collaterals.

Untreated. these aneurysms usually end in gangrene or rupture. They were formerly treated by one or other type of proximal ligature (see page 4059), but recently this has been abandoned for more direct methods. When possible they should be dealt with by excision, with reconstruction of the artery. In cases in which this is not possible, Matas's obliterative endo-aneurysmorrhaphy finds its most frequent and successful application.

Intra-cranial Arterial Aneurysms

Great interest has been aroused, both in this country and in America, in the origin, diagnosis, and treatment of arterial and arterio-venous aneurysms in the skull (see also pages 4049 and 5498). Arterio-venous (carotid-cavernous) aneurysms present very special problems, and are discussed in another section (see page 4079). Arterial aneurysms are at least as frequent and are certainly more interesting from a neurological point of view.

Although *arterial aneurysms* may develop in and outside the brain in the same way as aneurysms elsewhere, i.e. from *arteriosclerosis, syphilis. septic embolism* (mycotic), and from the *erosion* of neoplastic or infective lesions, the large majority of them are *congenital* in origin. It is particularly with these congenital aneurysms that we are concerned here; the other varieties are not as yet of much surgical interest.

Intra-cranial aneurysms are seen mostly in relatively young patients, with otherwise quite healthy arteries. Their usual situation is in the arteries of the base, and somewhere near or actually in the circle of Willis; the posterior and anterior communicating arteries are favourite sites. They are often multiple, may be very small, or as large as a walnut, and their spherical shape has given them the name of "berry aneurysms." Although occasionally growing into the brain, much more frequently they lie in the subarachnoid space.

Their chief surgical interest lies in their tendency to *spontaneous rupture*, with the production of a sudden and severe *subarachnoid*

hæmorrhage (see also page 5481). The patient often survives the first hæmorrhage, but recurrences are likely, and any of them may prove fatal. Rarely, the aneurysm does not rupture into the subarachnoid space, but leaks or ruptures into the cerebrum.

Pre-rupture diagnosis is essentially in the province of the neurologist, and can only be discussed briefly here (see also page 5481). The suggestive clinical features are: (1) Recurring migraine-like headaches; (2) involvement of cranial nerves, especially III, IV and VI; (3) loss of visual acuity; (4) pain in the distribution of the trigeminal nerve; and (5) occasionally, symptoms of VII or VIII nerve involvement, and of cerebellar involvement. Various combinations of these symptoms occur, most of them may be absent, and they may all be occasioned by other intra-cranial conditions. Pre-rupture diagnosis is thus extremely difficult, and is only occasionally made. In rare cases auscultation of the skull with a stethoscope reveals a bruit.

Of recent years *radiological* examination has provided much-needed assistance. A stereoscopic X-ray examination of the skull may show a rounded shadow near the brain base. Very recently *cerebral arteriography* (see also page 5483) has been attempted on a large scale by Moniz of Lisbon, and this promises to be of real value in the diagnosis of intra-cranial aneurysms; by this method about 10 cc. of thorotrast is injected into the common or internal carotid, after the artery has been exposed under local anæsthesia.

The diagnosis of *subarachnoid hæmorrhage* is not difficult, and when it occurs spontaneously it is strongly indicative of ruptured intra-cranial aneurysm. Often after a sudden strain, or exposure to strong sunlight, the patient is suddenly seized with violent pain in the occipital region and back of the neck. The pain becomes excruciating, and is soon followed by nausea and vomiting. The patient gradually loses consciousness, but may not do so completely, and passes into a state of cerebral irritation and stupor. The temperature rises to 102 degrees or more, and there is photophobia and marked restlessness. Rigidity of the back of the neck is a common and important sign, but deep tenderness in the nape of the neck is even more constant. Kernig's sign is also generally positive.

The symptoms and signs are obviously those of *meningeal irritation*, and many so-called cases of sunstroke in this country are doubtless examples of ruptured aneurysm. The diagnosis is definitely confirmed by *lumbar puncture*, which yields a deeply blood-stained fluid.

Surgical Treatment.

The treatment of spontaneous subarachnoid hæmorrhage has so

far been completely ineffectual. Medical measures do little or nothing to arrest the bleeding, or to prevent recurrence. Measures which lower the intra-cranial pressure (rectal mag. sulph., intravenous hypertonic saline, repeated lumbar puncture, and decompression operations) may relieve cerebral compression, but unfortunately they also tend to increase the bleeding. Nevertheless, one may be forced to use them when increasing compression of the brain threatens to destroy the patient. Fortunately, the hæmorrhage ceases spontaneously in many cases if the patient is left alone and treated with sedatives; but subsequent recurrence is almost certain.

Surgical attack on the aneurysm has until quite recently proved both dangerous and unsuccessful. Ligature of the carotid in the neck usually fails to prevent further ruptures, and, owing to the already impaired circulation in the skull, entails a grave risk of cerebral complications, which include embolism. Intra-cranial attack on the aneurysm by excision or ligature has proved uniformly fatal. In 1933, however, Dott of Edinburgh exposed a leaking aneurysm at the origin of the anterior and middle cerebral arteries, through an osteoplastic flap, and packed muscle grafts round it. This stopped the bleeding, and the patient, who had had three severe hæmorrhages in a fortnight, made a complete recovery, and was quite well two years later. Dott's courageous and intelligent procedure opens up a new and very promising field in the surgical treatment of this dangerous lesion.

Mention must also be made of Babcock's suggestion to treat intracranial aneurysms by an arterio-venous anastomosis (see page 4062). The procedure he suggests is an anastomosis between the *cranial* end of the common carotid and the *cardiac* end of the jugular vein; the object is to diminish the amount of blood reaching the aneurysm, and also to provide a channel whereby blood can escape from the aneurysm into the heart. We do not know whether this operation has actually been performed on a human subject, but it is certainly worthy of trial.

Arterio-venous Aneurysms

Any abnormal communication between an artery and a vein is known as an arterio-venous aneurysm. The great bulk of cases are traumatic in origin, although both congenital and spontaneous groups occur. Originally described by William Hunter, in 1757, the lesion was of

interest in the last century chiefly as a complication of venesection. The occurrence of a large number of cases during the Great War reawakened surgical interest, while of recent years this has been largely focussed on the treatment of one rather common example of the lesion, viz. carotid-cavernous aneurysm.

Pathology.

Arterio-venous communications are of two types: (1) *Aneurysmal varix* (figs. 2215 and 2216), in which there is a simple fistulous opening between closely adjacent vessels (direct communication); and (2) *varicose aneurysm*, in which an arterial hæmatoma forms between artery and

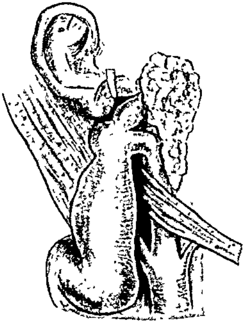

Fig 2215.—Arterio-venous aneurysm of external carotid artery and external jugular vein. (*Modified from Mont R Reid.*)

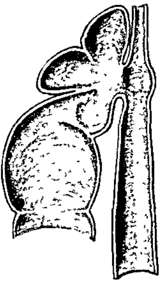

Fig. 2216. Section of specimen depicted in Fig. 2215.

vein, and, becoming surrounded by a connective tissue proliferation, develops into a false aneurysm, into which both the artery and the vein open. Both types are common, although varicose aneurysms predominate in the limbs.

Ætiology.

More than 90 per cent of cases are *traumatic* in origin. Of 447 cases collected by Callander, 189 were caused by bullets and shell fragments, 161 by stab wounds, and 28 by contusions. Arterio-venous aneurysms in the limbs are almost always caused by injuries which involve both artery and vein simultaneously. Such injuries are either lateral wounds or perforations. Carotid-cavernous aneurysms, however, usually result from tearing of the artery alone, the common cause being

a fracture of the middle cranial fossa. Fractures are an occasional cause in the limbs.

Congenital cases are rare, and tend to be multiple. The writer has recently seen a child of seven with a congenital aneurysm between the superficial temporal artery and vein, who had had a similar tumour removed from the forearm some years previously.

Spontaneous cases are rarer still, and are generally produced by rupture of an arterial aneurysm into a neighbouring vein. They are mostly seen in connection with the aorta and the great veins near it.

Morbid Anatomy.

The sites of election for traumatic arterio-venous aneurysms are those in which an artery and vein are enclosed in the same sheath, in an exposed position. They are specially common in Scarpa's triangle, the thigh, the popliteal space, the triangles of the neck, the axilla, the antecubital fossa, and the cavernous sinus.

In the course of development of the aneurysm important changes occur in the vessels themselves, in the fistula or sac between them, and in the local and general circulation. Recent work shows that the most important morbid changes are those which affect the heart.

(1) *Changes in the Vein.* Under the unaccustomed arterial pressure to which it is subjected, the vein dilates both above and below its communication with the artery; at the same time the venous wall becomes hypertrophied or *arterialised*, and tortuous. At first, these changes are localised, but gradually the dilatation spreads distally, and sometimes proximally, until very extensive phlebectases may result. At times the venous dilatation proceeds to an almost grotesque degree. The blood-pressure in the vein may reach 80 or 90 mm.

(2) *Changes in the Artery.* Distal to the aneurysm, the arterial pressure falls and the artery becomes contracted, but proximally it dilates (fig. 2217). In large communications that have existed for months or years the proximal dilatation of the artery may be marked, and may extend for a considerable distance. Degeneration may follow in this dilated portion, and even secondary aneurysms have been known to develop from it.

(3) *Changes in the Communication.* When the communication is a simple fistula (aneurysmal varix) it gradually becomes narrowed by a growth of fibrous tissue round it. Sometimes the contraction of the fistula proceeds to obliteration and a natural cure. In the case of varicose aneurysms, the wall of the intervening sac thickens by increasing fibrous condensation, while its lining becomes gradually covered by endothelium growing from the artery. The sac shows little or no

tendency to enlarge; indeed it mostly tends to shrink. The increasing size of the "tumour" is almost entirely produced by progressive dilatation and tortuosity of the vein. Occasionally, an additional sac develops from the artery on the side away from the aneurysm.

(4) *Effects on the Local Circulation.* The pressure in the vein rises to near the arterial level, and there may be definite venous pulsation. Distal to the aneurysm there is bound to be a degree of arterial deficiency

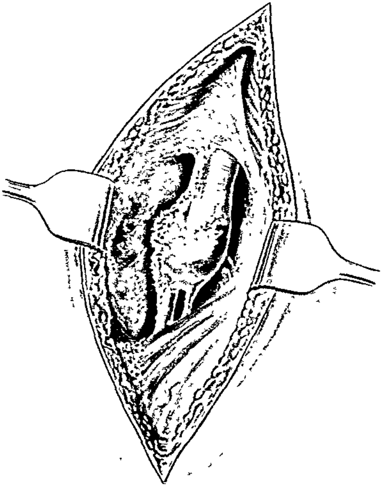

Fig. 2217.—Arterio-venous femoral aneurysm. (*After Mont R. Reid*)

associated with venous stasis. As a result, the nutrition of the part suffers, and œdema, atrophy of the skin and muscles, thickening of the subcutaneous tissues, and occasionally even gangrene, may develop. These changes occur in spite of a very abundant development of collateral channels.

(5) *Effects on the Heart and General Circulation.* As long ago as 1913 Osler described two cases of arterio-venous aneurysm in which death occurred at an early age from heart trouble. A large number of

cases have been published since, which prove conclusively that the shunting of arterial blood into a vein, *when large vessels are concerned*, greatly adds to the strain on the circulation and to the work of the heart. Proximal to the fistula there is a great fall in diastolic arterial pressure, with a compensatory rise in the systolic pressure. The pressure conditions are very similar to those of aortic regurgitation. In addition, there is an increase in the amount of venous blood entering the heart, as well as in the total volume of circulating blood. The pulse is rapid and develops a water-hammer quality.

Under this vascular strain the heart begins to dilate. At first the dilatation is compensated by hypertrophy, but sooner or later decompensation sets in and ends in death. The rate and degree of the cardiac changes are governed by the size of the vessels and fistula. Removal of the aneurysm or closure of the fistula will lead to recovery of the heart, provided the change in circulatory conditions is not too abrupt.

Diagnosis.

A considerable interval usually elapses beween the causal injury and the discovery of the arterio-venous aneurysm. In part this delay may be due to blockage of the fistula by a hæmatoma or a thrombus, which is organised or absorbed later, but it may also be accounted for by the absence of noticeable signs at an early stage of the aneurysm. In congenital cases many years may pass before the patient's attention is drawn to the lesion; indeed cases are on record where the first symptoms which led to advice being sought were those of cardiac decompensation!

The outstanding *local signs* are the presence of a *pulsating lump*, which is usually quite small, *dilatation of veins*, and a characteristic *thrill* and *murmur*.

The *pulsating lump* is mostly produced by great distension of the vein near the fistula. In varicose aneurysm the sac between the artery and vein may also be palpable, but tends to be obscured by the dilated vein. As distinct from arterial aneurysms, the lump is usually small or moderate in size, and does not tend to enlarge.

As a general rule, especially in the lower limb, there is marked *dilatation of the veins* beyond the aneurysm, and not infrequently this leads to a wrong diagnosis of varicose veins. The limb suffers from venous stasis, and may show atrophic and hyperplastic changes, perhaps proceeding to ulceration.

The *thrill* and *murmur* are absolutely diagnostic. Over the aneurysm both are *continuous*, but they show *systolic intensification*. The thrill has a definite "purring" quality, while the murmur has been likened to

the buzzing of a bluebottle imprisoned in a paper-bag. Both thrill and murmur reach their highest intensity at the fistula, where the murmur is also at a higher pitch than elsewhere; this sign assists the exact localisation of the fistula in small or deep-seated aneurysms. The thrill and murmur are transmitted for some distance, both proximally and distally, but away from the aneurysm they lose their continuous nature and become rhythmical and systolic; on compression of the artery proximal to the aneurysm, the thrill and murmur disappear.

General symptoms occur only when fairly large vessels are involved. *There is usually some tachycardia, with a pulse-rate of 80 to 100.* On compression of the aneurysm, the pulse may become slow and the diastolic pressure may rise. This is known as Branham's sign, and is of prognostic importance, as it shows that the heart muscle is not seriously affected. The water-hammer pulse and capillary pulsation may be present with large fistulæ. Cardiac enlargement and decompensation may be the outstanding symptoms when the arterio-venous fistula is between large vessels.

Differential diagnosis from arterial aneurysm presents no difficulty. The absence of progressive enlargement, the presence of a thrill, and the continuous nature of the murmur, should settle any doubt. The removal of oxygenated blood by aspiration of a vein near the fistula is a pathognomonic test. The distinction between aneurysmal varix and varicose aneurysm can sometimes be made by palpation. Otherwise assistance must be sought from radiography.

Treatment.

Small arterio-venous aneurysms, particularly when there is no interposed sac, require no treatment. Even a large aneurysmal varix is probably best left alone, unless it is interfering with the local or general circulation. On the other hand, most varicose aneurysms, and all fistulæ which threaten the well-being of the limb, or produce the least signs of circulatory or cardiac embarrassment, should be operated on.

If an operation is performed at the time of the original injury every effort must be made to preserve the continuity of the vessels, when these are of importance to the vitality of the part. Since the vascular injuries are always partial, both the arterial and the venous wounds can be repaired by lateral suture.

As a rule, however, the case is not seen until some days or weeks have passed. Under such circumstances a period of *delay* is advisable, to allow the vessels and other tissues to recover from the initial trauma, and also to give time for the development of an adequate collateral circulation.

The following *operative measures* are available for the treatment of arterio-venous aneurysms: (1) Proximal ligature of the artery; (2) proximal and distal ligature of the artery; (3) ligature of the vein; (4) quadruple ligature; (5) ligature of the fistula; (6) restorative procedures; and (7) excision.

Proximal ligature is dangerous, whether it is near the aneurysm or at a distance. In the extremities it is often followed by gangrene, while ligature of the carotid for cavernous aneurysm may cause cerebral complications. The danger of ligature can be diminished by performing partial occlusion (with metal bands), or by employing intermittent compression for a period, with the object of enlarging the collateral paths.

Double ligature of the artery may be performed for small varicose aneurysms, but it is preferable to tie the vein as well.

Ligature of the vein is of little use, as it merely converts the aneurysm into an arterial one.

Ligature of the fistula may be attempted for an aneurysmal varix with a narrow communication, but there is danger of the ligature cutting through.

Quadruple ligature (double ligation of artery and vein) with *excision of the aneurysm* is the best procedure for cases unsuitable for reconstructive surgery. This may entail a tedious and difficult dissection, but it is safer than quadruple ligature alone, which is very liable to be followed by gangrene. *An efficient collateral circulation is, of course, vital to the success of these operations*, and every effort must be made to improve it by preliminary compression and other measures. When the vitality of the part is in doubt, the surgeon has no choice but to attempt a restorative procedure, even if the chances of a successful issue are small.

Restorative procedures should be aimed at for all large fistulæ. An aneurysmal varix is best repaired by opening the vein opposite the communication, after provisional arrest of the circulation (see page 4083), suturing the fistula from that aspect, and then repairing the incision in the vein. When the fistula is wide and short, it may be wiser to divide it from the outside, and then to suture the lateral wounds of the artery and vein thus produced (for vascular suture see page 4084).

For a varicose aneurysm the ideal procedure is excision of the sac and repair of the lateral openings in the artery and vein by suture. In difficult cases the vein should be excised with the sac, and only the artery repaired. When the sac cannot be isolated with safety, some form of endo-aneurysmorrhaphy is indicated; the simplest procedure is to

expose part of the sac and open it, and then to suture the arterial and venous openings as well as any collaterals, from within the sac. The sac itself is obliterated by invaginating sutures.

CAROTID-CAVERNOUS ANEURYSMS

This is one of the most common forms of arterio-venous aneurysm; in 1935 Dandy stated that there were over 800 cases in the literature. In its cavernous part, the internal carotid artery is separated from the blood in the cavernous sinus by a single layer of venous endothelium. To produce an arterio-venous fistula, therefore, it is only necessary for the carotid artery to give way. More than three-quarters of the cases are *traumatic* in origin, the usual cause being a fissured fracture through the middle cranial fossa; gunshot wounds, and punctures of the orbit are occasionally responsible. The remaining cases are either *congenital*, or caused by atheroma or other degenerative *arterial disease.*

Clinical Features.

Symptoms may start soon after the injury, or they may be delayed for months. The main features are: (1) *Pulsating exophthalmos*; (2) *a subjective roar*, which may be continuous, or mostly systolic, is intensified by stooping, and may be diminished by compression of the carotid in the neck; (3) a systolic or continuous *bruit*, which can be heard over the temple, forehead or eyeball; (4) *pain* may or may not be present, and it may be local or take the form of a widespread headache; (5) *dilatation* of the orbital and perhaps the forehead *veins*; (6) swelling of the lids and conjunctiva (*chemosis*); and (7) *ophthalmoplegia* and *optic neuritis*, which vary in severity.

Treatment.

The aneurysm may be attacked either from the arterial or from the venous side; both methods aim at securing thrombosis in the fistula itself, or on one or other side of it, in the hope that this will be followed by fibrous obliteration of the fistula, and so produce a cure of the aneurysm.

Attack from the *venous side* has been carried out by ligature of the ophthalmic veins, by diathermy, and by injection of sclerogenic and coagulating solutions into the ophthalmic veins. None of these methods has proved really successful, although occasional benefit appears to result.

Arterial attack usually consists of ligature of the common or internal carotid in the neck. Ligature of the *internal carotid* is the better procedure, but if the common carotid is occluded the external carotid should be ligated also. Unfortunately 15 to 20 per cent of cases treated

in this way develop cerebral trouble, which may prove fatal. To prevent this, Matas in 1935 advised preliminary intermittent compression, which should be done by the patient, or by a team of assistants, and continued until long periods of compression produce no cerebral symptoms. As an alternative, the carotid occlusion may be done gradually, by using metal bands which are tightened in stages.

Carotid ligature always produces an immediate improvement, with cessation of the distressing roar, retraction of the eyeball, and improvement of vision: but in 24 hours some of the symptoms begin to

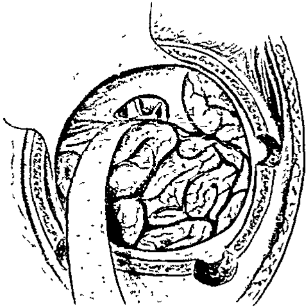

Fig 2218.—Dandy's intra-cranial carotid occlusion for carotid-cavernous aneurysm. (*After Dandy*)

return. Whether permanent relief is obtained or not depends on efficient occlusion of the fistula by thrombosis and organisation of the clot. Matas states that 40 to 50 per cent of cases are cured, and others relieved, but some 30 per cent or so ultimately relapse.

For relapsed cases after ligature of the carotid in the neck, Dandy recommends an intra-cranial occlusion of the internal carotid by a silver clip (fig. 2218), after it emerges from the cavernous sinus and parts with its ophthalmic branch. He employs the frontal pituitary approach through a trap-door osteoplastic flap, and has performed the operation twice with marked success. The procedure is a distal ligature on the *Brasdor principle*.

Cirsoid Aneurysms

A cirsoid aneurysm is a remarkable development of dilated and tortuous vessels, forming a characteristic vascular tumour, which has been likened to a mass of pulsating worms. It is mostly seen in the *scalp*, particularly in the distribution of the temporal and frontal vessels. The condition is nearly always *congenital* in origin, but *trauma* seems to play a contributory part in its causation. Although it may start quite early in life, some cases do not begin until puberty or later, but even these usually develop in a congenital vascular defect, such as a *nævus*.

The *pathogenesis* of this interesting lesion undoubtedly depends on the existence of multiple *congenital arterio-venous communications*. In a region so full of blood-vessels as the scalp, it is evident that these fistulæ will result in what amounts to numerous arterio-venous aneurysms. The vessels undergo the changes one might expect (see page 4047). The veins dilate, and become tortuous and thick-walled ; they pulsate and are, in fact, arterialised. The arteries also dilate and degenerate, and secondary aneurysms develop from them. Owing to pressure-erosion the dilated arteries and veins break into one another, with the formation of secondary communications. In this manner, a kind of vicious circle is produced, more and more vessels are involved, and the lesion increases in size and extent, until almost the whole scalp is involved. In the worst cases the skull becomes eroded.

Clinical Features.

The diagnosis of the condition presents no difficulties. The mass of *tortuous, dilated and pulsating vessels cannot be anything but a cirsoid* aneurysm. The most distressing symptom is a *constant humming noise*, which is very disturbing to the patient, and may lead to nervous complications. It is, of course, easily heard on auscultation. Severe headache and a sense of heat may also be complained of.

Treatment.

An enormous variety of therapeutic procedures have been tried, but most of them have ended in failure. This is particularly the case with injections of sclerosing and coagulating substances, and with the older procedures of cauterisation and electropuncture. But it also applies to limited ligature operations.

A small area of cirsoid formation can be completely excised with little risk of recurrence. But a large lesion is both difficult and dangerous to treat by radical methods, unless these are conducted in

stages designed to lessen the size and vascularity of the mass, prior to excision.

The following procedure for large cirsoids is recommended by McNealy: the first step is *preliminary ligature of the external* carotid. After a week, this is followed by ligature of main branches, such as the superficial temporal, posterior auricular, etc. After another week, the large vessels entering and leaving the tumour are tied near its edge. These procedures will reduce the size and the intense vascularity of the tumour to such an extent that excision of the whole mass, or of the greater part of it, becomes feasible, and is freed from the danger of uncontrollable hæmorrhage.

Cirsoid aneurysms occasionally occur in the limbs, and very rarely in the brain.

CHAPTER V

Suture and Ligature of Arteries

ARTERIAL SUTURE

Suture of arteries has become a safe and satisfactory operation. The reasons for its recent success include reliable asepsis, apposition of intima to intima, the use of fine vaselined or oiled silk, and the exercise of meticulous care and gentleness. By these means thrombosis can be averted, especially in healthy arteries. Arterial suture has revolutionised the treatment of wounds of large vessels, such as the common carotid, subclavian, axillary, external iliac and common femoral. It also forms an essential part of the operations of embolectomy and aneurysmorrhaphy.

The following rules must be strictly observed: (1) Absolute asepsis is essential; (2) the intima of one side of the wound must be brought into accurate apposition with the intima of the other side, and no part of the media or adventitia should be allowed to come in contact with the blood stream; (3) the greatest care must be taken to avoid injury to the arterial wall, especially to the intima; (4) the intima must be kept moist with citrate solution, and should not be scratched or picked up with forceps during the suture; and (5) the choice of needles, sutures, etc., should be governed by the need to avoid thrombus formation.

In the actual *technique* of suture, the first step is adequate exposure of the wounded artery, and the second step is the *temporary occlusion* of the vessel. It is essential that this occlusion be effected without inflicting the slightest damage on the arterial wall. For the closure of a small punctured wound efficient hæmostasis can be obtained by gentle compression of the artery with the fingers of an assistant, or by passing a piece of broad tape round the artery and holding it moderately taut. For more serious wounds, which will require more time, the best agent to employ is a smooth-jawed, rubber-covered artery clamp, with a rather weak spring.

There are two types of arterial suture, *lateral suture* (see fig. 2219) and *end-to-end anastomosis* (see fig. 2220). In both it is necessary to

evert the edges, so that intima is brought into contact with intima. This is best done with interrupted mattress sutures, using very fine sharp needles, and the finest oiled or vaselined silk. Very fine catgut has also been used with success, but it is undoubtedly safer to employ silk. The everted edges are then further secured with a few interrupted sutures, and the clamp released.

In *end-to-end anastomosis* for a complete division or rupture of a large artery, some difficulty may be encountered in bringing the retracted ends together without tension, but unless this can be done the operation should be abandoned for ligature. Sometimes a segment of the artery may have to be excised because it is extensively bruised,

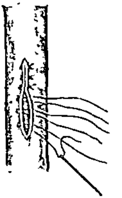

Fig 2219.—Suture of lateral wound of artery

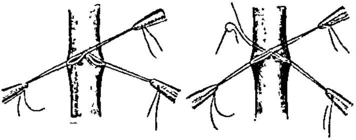

Fig 2220.—End-to end anastomosis of artery.

or for some other reason (see page 4020). In many cases even a wide gap can be bridged successfully by positional relaxation (e.g. flexion of the thigh for the femoral artery), or by freeing both ends of the artery for some distance by careful dissection. Having obtained an easy apposition, the actual anastomosis is greatly facilitated by passing three traction sutures at equidistant points, so that when these are pulled on the anastomosis is *converted into an equilateral triangle* (fig. 2220). Each side of the triangle is now sewn separately, with everting mattress sutures. After release of the artery clamps, the suture line must be carefully watched for a few moments, as it may be necessary to reinforce it.

During the performance of arterial suture, provision must be made to prevent clot formation. The wound and the lumen of the occluded artery may be washed with sodium citrate solution, or the intima of the artery at and near the suture should be lightly smeared with sterile paraffin.

Exposure and Ligature of Arteries

GENERAL PRINCIPLES

Ligature of an artery is mostly needed for the *arrest of hæmorrhage*, which is usually caused by an external wound, accidental or operative ; arterial hæmorrhage may also be produced by subcutaneous rupture of a vessel, or by its invasion in an erosive or ulcerative process. Under these conditions the surgical procedure employed for the arrest of bleeding is always more or less an emergency operation.

There are, of course, many other indications for arterial ligature. Its employment in various forms of *aneurysm* has been fully considered. It is also used in the treatment of *toxic goitre*, to diminish the size of some *tumours*, and in the course of many *surgical operations*, e.g. as a preliminary to resections of the tongue, colon, uterus, etc.

The ligature of *small arteries* is hardly ever done except for the arrest of bleeding. When the artery is completely divided, both ends are picked up as cleanly as possible (i.e. with a minimum of surrounding tissue) by artery forceps, and tied moderately firmly with a reef-knot of rather fine catgut. An intact artery which is exposed during an operation and which needs division, also an artery which is incompletely severed, should be picked up with two pairs of forceps, and divided between them ; it is then treated as a divided artery.

Ligature of a *large artery* is an important surgical operation, by no means free from risk. Classical methods of exposure and ligature are now of chief interest to candidates for the operative surgery examination, and have been very largely replaced by methods better adapted to modern requirements. There are certain *principles* and *general rules* which govern modern ligature procedures, and which are tabulated below :

(1) *Incisions* along the anatomical line of an artery do not always provide the best access to an injured vessel. In the types of injury prevalent in these times (traffic and industrial injuries, and war wounds) very free exposure is often needed, since other important structures besides arteries will be damaged. *The incision must, therefore, be planned to provide the necessary exposure for each individual case.*

(2) *Arteries should not be tied in continuity*, unless the occlusion is to be temporary. Ligation in continuity is often followed by absorption of the ligature and recanalisation or absorption of the thrombus. When an intact artery is to be occluded, it should be tied in two places,

and divided between the ligatures. These should be placed a fair distance apart, so that a good cuff projects from each end; the cuffs granulate and develop into firm plugs of fibrous tissue.

(3) The ligatures should be tied firmly enough to *damage the intima* (otherwise clotting will not occur), but *not so as to rupture the media.* After ligation, thrombosis extends up to the nearest collateral, and by organisation converts the artery into a fibrous cord.

(4) The danger of fracturing the arterial wall is particularly great in large arteries, the damage being done by the force of arterial pulsation against the tightening ligature, rather than by the ligature itself. In such cases there is a real risk of the ligature cutting right through the arterial wall, with fatal hæmorrhage. To avoid this danger, Reid advised (1934) that the artery should be temporarily occluded by proximal and distal compression during the application and tying of the ligature.

(5) In the occlusion of large arteries *non-absorbable* ligature material should be employed. Catgut may begin to fray and be absorbed before the artery is safely consolidated. The thickness of the ligature depends on the size of the artery. Fine ligatures cut through the wall more rapidly than coarse. Arteries of large size are best tied by Ballance's stay-knot (fig. 2221). Coarser ligatures should be used for arteries tied in continuity than for a divided artery.

(6) The blood-flow in the territory of a ligated artery is re-established, in the first place, by vasodilatation of the collaterals. This vasodilatation, however, is temporary, and the ultimate fate of the ischæmic territory depends on the amount of permanent collateral supply which develops in time to keep the tissues alive. It has been shown conclusively that resection of a segment of the artery (arteriectomy) increases the vasodilator response, and so tends to preserve the vitality of the ischæmic area.

(7) Simultaneous *ligature of the companion vein* also quite definitely improves the blood supply of the territory of an occluded artery, and should always accompany ligation of a main artery. It acts by " balancing " the available circulation, by increasing the capillary tension, and by distributing what blood is left in the part. Although this procedure was warmly advocated by Makins many years ago, its general acceptance is of very recent date. Experimental work published by Brooks and Johnson in 1934 shows that by simultaneous vein ligature the incidence of gangrene was reduced from 29 per cent to 2 per cent.

(8) In general, a divided artery should be ligatured *where it is bleeding.* More proximal ligation may fail to arrest hæmorrhage,

owing to the presence of collaterals beyond the occlusion. The *distal end* must also be ligatured, whether it is actually bleeding at the time, or not; otherwise it will fill from collaterals and bleed later.

(9) After completing the ligation, the wound must be closed completely, and without drainage.

GENERAL TECHNIQUE

Temporary arrest of hæmorrhage, if any, has been already effected by a tourniquet, direct or indirect pressure, or by some other method (see pages 4003 and 4083). The patient or limb is placed in a suitable

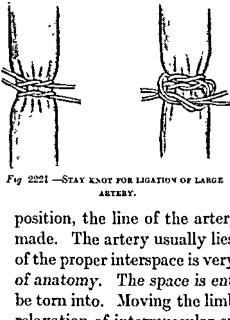

Fig 2221 —Stay knot for ligation of large artery.

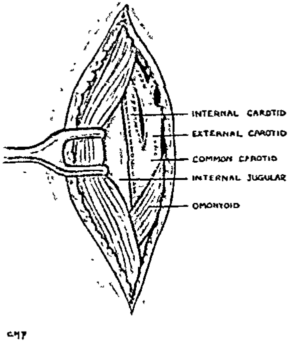

Fig 2222.—Exposure for classical ligature of the common carotid artery or its branches.

position, the line of the artery visualised, and an appropriate incision made. The artery usually lies in an intermuscular space. Recognition of the proper interspace is very necessary and requires a good knowledge of anatomy. The space is entered into with a scalpel, and must never be torn into. Moving the limb helps in both the identification and the relaxation of intermuscular spaces. The approach to the artery must not be through a shelving wound, since the deep parts require as free an exposure as do the superficial tissues. If the depths of the wound can be clearly seen, there is no difficulty in finding the artery, or in distinguishing it from accompanying veins and nerves.

The first view of the artery will be through its sheath. This is

picked up with toothed forceps and nicked with a fine scalpel on the flat. The lifted sheath is then divided for the distance required, and the artery freed with a dissector. Classically, the ligature is applied on an aneurysm needle, which is passed round the vessel, away from its most dangerous neighbour; with free exposure, however, it matters little how the ligature is placed round the artery. What matters is that the artery should be properly freed so that it is ligatured cleanly, that the ligature should be properly and securely (but not tightly) tied, and that the general principles just enumerated should be strictly observed.

EXPOSURE AND LIGATURE OF THE LARGER ARTERIES

Common Carotid Artery (see also Vol. II, page 1942).

(1) When the intact artery is to be ligated, e.g. for intra-cranial aneurysm, the *classical method* is quite adequate (see fig 2222). The shoulders are raised, a sand-bag is placed under the neck, and the head turned to the opposite side. A 3-inch incision is made along the front edge of the sterno-mastoid, its centre being opposite the cricoid. The external jugular vein is identified and retracted, or divided between ligatures. The deep fascia is incised, the sterno-mastoid retracted outwards, and the anterior belly of the omo-hyoid looked for and hooked down. The carotid sheath is now easily seen. It is opened on its inner side, avoiding the ansa, and the common carotid is brought into view near its bifurcation. Care must be taken to separate the artery from the internal jugular vein, which overlaps it, and from the vagus nerve, before applying the ligature. Fascial strips or tape are preferable to other ligature materials.

(2) For gunshot wounds and other injuries implicating the common carotid or its branches, a much more *extensive exposure* will be required (fig. 2223). A flap should be raised down to the deep fascia, the incision running along the front edge of the sterno-mastoid to the sternum, and then along the upper border of the clavicle. The flap is turned back and the deep fascia carefully incised along the sterno-mastoid border. A finger is passed under the sternal and clavicular heads of the muscle, and these are divided an inch or so above their origins. The sterno-mastoid is now retracted backwards, and the omo-hyoid hooked downwards. The carotid sheath is thus exposed through its entire length, and the common, external, or internal carotid arteries, as well as the internal jugular vein, can be dealt with as required. At the end of the operation the sterno-mastoid is reconstructed with mattress sutures.

External and Internal Carotid Arteries.

(1) For ligature of the intact arteries, the *classical method*, as described for the common carotid, will give all the access required. By centring the incision on the cricoid, not only the carotid bifurcation, but also the *origins* of the internal and external arteries, are easily brought into view. When it is desired to tie the external carotid higher

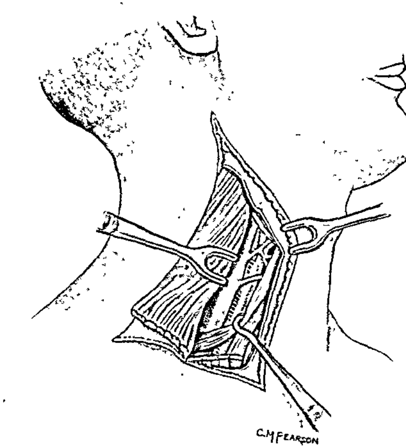

Fig. 2223.—Wide exposure of carotid vessels for wounds of neck.

up or to ligate one of its branches (e.g. the lingual, superior thyroid, or facial), the incision is made at a slightly higher level.

After incising the carotid sheath, the jugular vein is freed and retracted *inwards*, and the carotid bifurcation is exposed. The external carotid can be distinguished from the internal by the fact that it gives branches. Care must be taken not to injure the hypoglossal nerve, its descendens branch, or the superior laryngeal nerve which lies deep to both carotid arteries.

(2) For *deep wounds high in the neck*, in which an injury of one of the carotids, or of a large branch, is suspected, a particularly *free exposure*

is essential (fig. 2224). The best incision is one which runs up the anterior border of the sterno-mastoid from the cricoid to the mastoid process, and then curves back over the latter. The tip of the mastoid is detached with a chisel, and pulled back with the sterno-mastoid muscle. The posterior belly of the digastric is now seen, freed carefully, and divided on a director. A very complete exposure of the upper part of the carotid vessels and jugular vein is thus obtained, as well as of most branches of the external carotid. At the end of the operation, the two

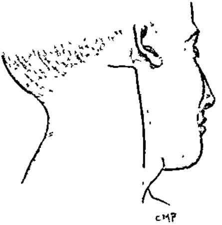

Fig 2224.—INCISION FOR EXPOSURE OF UPPER CAROTID REGION.

halves of the digastric are stitched together, while the tip of the mastoid is re-attached with sutures through the periosteum.

Subclavian Artery (see also Vol. II, page 1951).

The *classical methods* of ligaturing the subclavian give a very cramped approach particularly in stout and short-necked patients. Except for being severe tests of surgical skill, they have nothing to recommend them, and are quite unsuitable for the treatment of wounds.

The *modern method* entails division of the clavicle and provides the exposure which is needed in the treatment of injuries (fig. 2225). The patient lies with his shoulder over the edge of the table and a sand-bag under his back. The incision is roughly T-shaped, the horizontal part just above the clavicle, and the oblique part from near the inner end of the first incision, downwards and outwards in a curved manner, to the axilla. The pectoralis major is completely divided in the line of the oblique incision, and the pectoralis minor is cut across near its insertion, after it is hooked up with the finger. The exposed costo-coracoid membrane and deep pectoral fascia are now incised up to the clavicle. The clavicle is then cleared a little medial to its centre, two

holes are drilled through it, and it is divided with a small saw or chisel between the drill-holes ; a guard must be inserted under the bone while this is done.

This approach provides a wonderful exposure of a region of the utmost importance, and gives access to both the subclavian and the

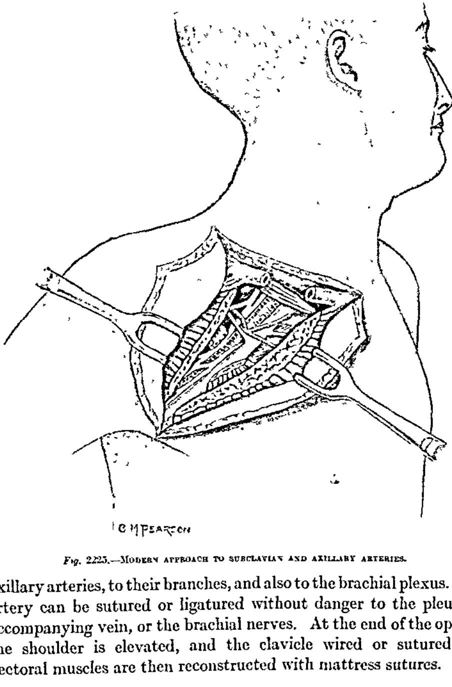

Fig. 2225.—Modern approach to subclavian and axillary arteries.

axillary arteries, to their branches, and also to the brachial plexus. Either artery can be sutured or ligatured without danger to the pleura, the accompanying vein, or the brachial nerves. At the end of the operation the shoulder is elevated, and the clavicle wired or sutured. The pectoral muscles are then reconstructed with mattress sutures.

Axillary Artery.

The first and second parts are best exposed by the preceding method,

although the *classical ligature of the first part* is a very pretty examination exercise, and deserves a brief description. A curved incision is made half an inch below the middle two-fourths of the clavicle. The pectoralis major is incised through its whole thickness, and the pectoralis minor retracted downwards. The costo-coracoid membrane is then divided along the upper border of pectoralis minor, care being taken not to injure the axillary vein, which is attached to it. The axillary artery is now exposed, with the vein on its inner side, and the brachial cords outside and behind it. An aneurysm needle is passed from the inner side, to avoid the vein.

The *third part* of the axillary artery can be exposed by an upward prolongation of the incision for the brachial artery. Care must be taken of the basilic vein, which is here joining the brachial venæ comites to form the axillary vein, on the inner side of the artery. The cords of the brachial plexus are giving off their respective nerves, and are disposed on all sides of the artery. They must be identified and hooked out of the way.

Brachial Artery.

The *classical approach* gives an adequate exposure of the brachial artery. The arm should be abducted, with the forearm (not the upper arm) resting on a small table, while the surgeon sits between the patient and the arm. A free incision is made in the line of the artery (middle of clavicle to middle of antecubital fossa), between the inner head of the triceps, on which the artery lies, and the belly of the biceps, by which the artery is overlapped. The biceps is now retracted upwards (towards the ceiling), care being taken not to include the artery in the retractor. The median nerve is usually seen first as it is crossing the artery from without in: it is freed and pulled out of the way. The artery is then dissected away from its accompanying veins, and dealt with.

Bifurcation of the Brachial Artery and its Branches (fig. 2226).

Wounds in the antecubital fossa and the upper part of the forearm may implicate any one or more of the following arteries: the brachial, the ulnar, the radial, the common interosseous, or their branches. The freest possible exposure is therefore necessary for arterial injuries in this region. The position of the arm is as for ligature of the brachial artery. A 4-inch incision is made, starting well above the antecubital fossa and to the inner side of the biceps tendon, and curving downwards and inwards over the supinator longus. The deep fascia and the semilunar expansion of the biceps are incised, after ligating the median basilic vein. The space between the supinator longus and pronator teres is opened up by wide retraction of these muscles, after the inter-

muscular interval is defined by running a dissector down it. The end of the brachial artery is now seen, with the radial and ulnar arteries arising from it, and the median nerve on its inner side. By rotating the hand, and retracting more forcibly the muscle which is mostly in the way, either main branch can be followed for some distance; the common interosseous can also be exposed for the short portion above the hiatus between the oblique ligament and the upper edge of the interosseous membrane.

Iliac Arteries.

The *common* and *internal iliac* arteries should always be exposed by the transperitoneal route. The abdomen is opened by a median sub-umbilical incision, the patient placed in the Trendelenburg position,

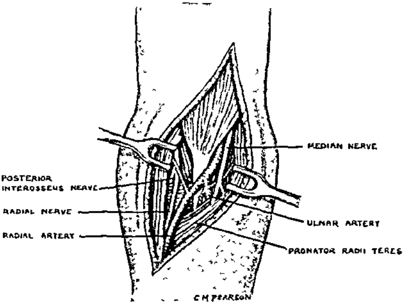

Fig 2226.—Wide exposure of arteries in antecubital fossa and upper third of forearm.

and the intestine packed out of the way. The desired artery is easily found, the peritoneum over it is incised, and the artery cleared and dealt with. The ureter must always be identified, as it crosses the bifurcation of the common iliac artery, and runs down the lateral pelvic wall in front of the internal iliac vessels.

The *external iliac* artery is best approached by a modification of Abernethy's classical extra-peritoneal method: An incision is made $\frac{3}{4}$-inch above the outer two-thirds of Poupart's ligament. The external oblique aponeurosis is divided, the inguinal canal opened up, and the arching fibres of the internal oblique defined and incised near their origin from Poupart's ligament (fig. 2227). The deep epigastric vessels are now seen and divided between ligatures. The transversalis fascia is exposed in the floor of the wound and is incised, also near its

attachment to Poupart's ligament. This exposes the peritoneum, which is peeled off the psoas and iliacus with the fingers. The external iliac vessels are thus brought into full view (fig. 2228).

Femoral Artery.

The *common femoral* should not be ligatured owing to the grave risk of gangrene; every effort must be made to reconstruct the artery in cases of injury, by lateral suture, or even by end-to-end anastomosis. When ligature cannot be avoided, the vein should be tied as well.

Exposure of the *superficial femoral* (fig. 2229), either in Scarpa's triangle or in Hunter's canal, is quite easy. The thigh is slightly flexed, abducted, and everted. An incision is made in the line of the artery (from the mid-point between the anterior superior spine and the symphysis to the adductor tubercle). The fascia lata is divided, and the flat sartorius

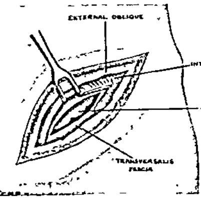

Fig 2227.—LIGATURE OF EXTERNAL ILIAC ARTERY. 1st Stage

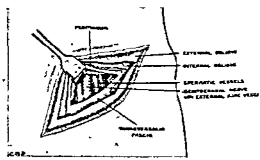

Fig 2228.—LIGATURE OF EXTERNAL ILIAC ARTERY. 2nd St

belly identified and retracted; to expose the artery in Scarpa's triangle, the sartorius is pulled outwards, but in Hunter's canal a better approach is provided by retracting the muscle inwards. In the triangle the artery is exposed at once, but in Hunter's canal it lies embedded in some areolar tissue and roofed over by a fibrous expansion, and a little dissection will be needed to bring it into view.

Arteries in Upper Part of Popliteal Space.

The femoral artery where it comes through the adductor magnus, and the upper part of the popliteal artery, lie very deeply, and a *very free approach* is required to give adequate exposure in this important region. The leg is placed on a small table some distance away from the operating table, and is held by an assistant, with the thigh abducted and everted, and the knee flexed. The surgeon stands between the two tables, facing the inner aspect of the thigh. A long incision is made, starting at the adductor tubercle and running up along the line of the

artery. The sartorius is seen in the front part of the wound; it is freed with the finger and retracted forwards. The adductor magnus tendon is exposed in the middle of the wound, with the semimembranosus behind it. The adductor magnus tendon is freed from its connections with the finger, and retracted well back. The aponeurotic expansion between it and vastus internus is thus put on the stretch; it is carefully incised, and retracted, and the femoral artery is exposed in the lower end of Hunter's canal, with the vein behind it. After a little dissection, the artery can be followed through the adductor opening, and into the popliteal space.

Lower Part and Bifurcation of the Popliteal Artery.

The patient lies prone, and the foot is controlled by an assistant. A 4-inch vertical incision is made between the two heads of the gastrocnemius, which are identified, separated by dissection, and widely retracted. The external saphenous vein and nerve are previously looked for and hooked aside. The internal popliteal nerve is now seen, and under it are found the popliteal vessels, the artery being the deeper of the two. The nerve is gently hooked aside, and the vessels freed by dissection until they disappear under the soleus.

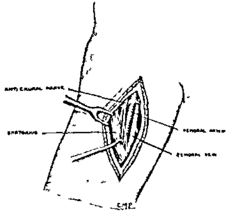

Fig 2229.—Exposure of femoral artery.

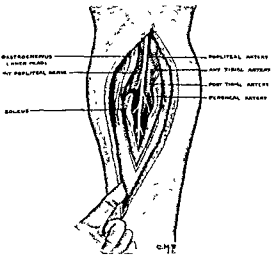

Fig 2230.—Exposure of vessels in popliteal space and back of leg.

If the surgeon desires to expose the popliteal bifurcation, or the origins of the anterior and posterior tibial and peroneal arteries, he can split the soleus on a director (fig. 2230). In this manner an excellent exposure is made of these vessels, and any injury of them can be dealt with, without incurring the great danger of gangrene which is associated with ligation of the popliteal artery itself.

Posterior Tibial Artery.

The *classical method* is another good examination test, but it gives

very poor access to the artery. The leg is flexed and rests on its outer side. A 4-inch incision is made an inch behind and parallel to the inner border of the tibia, down to the gastrocnemius. This is retracted away from the tibia, and the soleus is cut through well away from the inner edge of the tibia. The artery will be found external to the tibialis posticus, and embedded in the transverse intermuscular septum.

In the *modern method*, which gives a far better exposure (fig. 2230), the patient lies prone, with the foot over the end of the table. A long incision is made between the heads of the gastrocnemius and towards the medial side of the tendo Achillis. The short saphenous nerve and vein are seen and hooked aside. The gastrocnemius is now split between its two heads, and these are widely retracted. A finger is then pushed up under the soleus, and this is also split down its middle, and retracted. An excellent exposure is thus obtained of the posterior tibial vessels, as well as of the peroneal artery.

Anterior Tibial Artery.

The line of the artery is from a point midway between the head of the fibula and the external tuberosity of the tibia, to the mid-point between the two malleoli in front of the ankle. An incision is made along the line of the artery, which in its upper part lies deeply between the tibialis anticus, clothing the tibia, and the extensor longus digitorum, covering the fibula. Strong retraction of these muscles brings the artery into view. Lower down, the artery becomes superficial and can be reached with ease.

Gluteal and Sciatic Arteries.

Wounds of the buttock produce a hæmatoma under the gluteus maximus, and nothing short of a very free exposure will prove satisfactory in dealing with them. With the patient lying prone, a curved incision is made a little below the iliac crest and down towards the great trochanter. This exposes the dense gluteal aponeurosis, which is divided in the line of the skin incision. In this manner, the gluteus maximus is freed, and can be retracted well back, providing an excellent exposure of the pyriformis muscle, and of the gluteal and sciatic vessels and nerves. The gluteal artery is found above this muscle at its emergence from the great sciatic notch, while the sciatic artery is below it, running down a little distance medial to the sciatic nerve.

LYMPHATIC SYSTEM

CHAPTER I

Affections of the Lymphatic Vessels

by

Rodney Maingot

In this chapter the following conditions will be discussed:

(A) Injuries of the Lymphatic Vessels and of the Thoracic Duct.

(B) Inflammations of the Lymphatic Vessels—Lymphangitis:
  (1) Acute; (2) Chronic.

(C) New Growths of the Lymphatic Vessels—Lymphangiomata:
  (1) Capillary; (2) Cavernous; (3) Cystic Hygromata.

INJURIES OF THE LYMPHATIC VESSELS

With every surgical incision some lymphatic vessels are necessarily severed, but there is no noticeable discharge of lymph unless a large vessel or lymphatic trunk, such as the thoracic duct, is cut, a lymphangioma or cyst is incised, or an incision is made into an area where there is marked lymphatic obstruction, such as may occur in cases of elephantiasis.

Except in cases of an ordinary skin incision, there will, in each of the instances mentioned, be a discharge of lymph (*lymphorrhœa*), and where the thoracic duct is severed a *lymphatic fistula* may result. In the majority of cases, however, there is a cessation of the discharge as soon as healing of the wound takes place and new lymphatic vessels form.

INJURIES OF THE THORACIC DUCT

(A) *In the Neck*

The thoracic duct may terminate in several branches which open separately into the internal jugular and subclavian veins. When in the form of a single trunk, the duct will often be seen to enter the postero-lateral aspect of the union of these two large veins on the left side of the neck (fig. 2231). The right lymphatic duct may end as a single trunk and join the right subclavian vein, or it may take the form of several branches which open separately into the internal jugular and right subclavian veins. Division of the right lymphatic duct may occur during the performance of operations upon the neck, but is, as a rule, of no particular consequence.

Causes of Injury. These fall into four groups:

(1) Operations upon the neck: (*a*) for tuberculous glands; (*b*) for malignant glands; (*c*) for substernal goitre; (*d*) for thymic tumours; (*e*) for cystic hygromata; and (*f*) for phrenicectomy.

(2) Gunshot wounds, stabs, rapier thrusts, etc.

(3) Fractures of the sternum or clavicle.

(4) Compression or erosion due to growth.

Results of Injury. Following rupture or division of the thoracic duct in the neck there is a free discharge of clear limpid or milky fluid

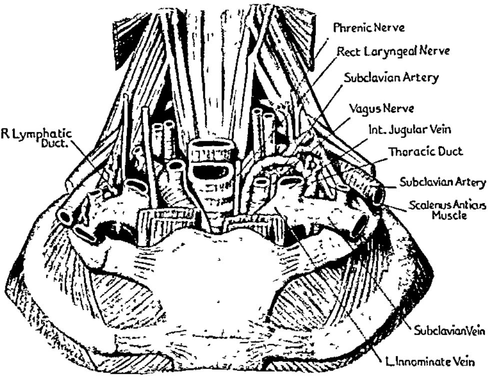

Fig. 2231.—The relations of the thoracic duct and of the right lymphatic duct in the root of the neck.

—chylorrhœa. Where the thoracic duct is present as a single trunk and this is severed, the results may be disastrous through loss of chyle, and may cause the patient to die from inanition. In cases of profuse chylorrhœa following such an accident there is marked thirst, progressive loss of strength, rapid emaciation, cyanosis and collapse, sometimes leading to an early fatal issue unless prompt and effective measures are taken to arrest the flow of lymph. Where the duct is composed of several branches and *all* of these are inadvertently cut, the same grave results will inevitably follow. Such an occurrence is, however, happily very rare, the more frequent accident being the severance of one or two of the main branches, causing a discharge which soon ceases

without producing much, if any, ill effect. If such an accident passes undetected at the time of operation it will later be evidenced by one of two *conditions*: (1) *A gradually increasing cystic swelling in the neck*; or (2) a lymphatic fistula accompanied by a profuse discharge of milky chyle.

Treatment. This depends upon whether the injury is recent or old.

(1) When the injury is recognised *during the performance of an operation*, both ends of the duct should be identified and ligatured. Likewise, if more than one large lymphatic vessel is cut, the individual ends of each should be picked up and tied. The surgeon who is anatomically minded will realise that ligature of the distal end of the duct is unnecessary, as the presence of valves at its termination will prevent any possibility of reflux. Theoretically, the ideal measure is to isolate the distal end of the duct and to anastomose it to the cut end of the external jugular vein or to the side of some large adjacent vein ; but in practice this operation, although it has been successfully performed on a few occasions, is often rendered difficult or even impossible owing to the small calibre of the thoracic duct.

(2) When a cystic swelling appears *subsequent to an operation* upon the lower part of the neck, and probing shows its contents to be chylous in nature, there are two methods which are commonly employed for arresting the flow of chyle. In the first, the patient is given large quantities of cream for a few days prior to operation, so that when the wound is reopened the welling up of white viscous chyle from the severed end of the duct will indicate the point of severance and permit of its being clipped and tied. The wound is then partly closed and drained. By the second method, the wound is reopened and tightly packed with gauze soaked in glycerine, firm pressure being applied to the area by means of a stout sorbo pad over a thick dressing of gamgee tissue.

(3) When a *lymphatic fistula* follows an operation upon the neck, the wound should be reopened and packed, and pressure applied.

(B) *In the Thorax*

Macnab and Scarlett have given the following classification of the *causes of chylothorax :*

(1) *Trauma.*

- (*a*) External violence :
  - (i) Closed trauma (there being no external wound or fracture), e.g. by falls from a height, run-over accidents, crushing between cars, buffer accidents, a weight falling upon the back, etc.
  - (ii) Trauma with fractured ribs, clavicle or vertebræ.

(b) Operative wound:
(i) Duct completely severed.
(ii) One or more terminals cut.
(c) Gunshot wound.
(d) Stab wounds, self-inflicted or otherwise.

(2) *New Growths and Granulomata*, e.g. carcinomata, lymphosarcomata, or tuberculous mediastinal glands, producing obstruction of the duct by pressure from without and leading to rupture.

(3) *Thrombosis of the Left Subclavian Vein.*
(4) *New Growths of the Duct itself.*
(5) *Perforating Lymphangitis.*
(6) *Aneurysm of the Duct.*
(7) *Cirrhosis of the Liver.*
(8) *Filariasis.*

In a general way it may be stated that roughly half the cases of chylothorax result from spontaneous rupture of the thoracic duct following obstruction or compression by new growth or tuberculous disease of the mediastinal glands, and the other half from trauma.

TRAUMATIC CHYLOTHORAX

This is a rare condition, there being less than 100 cases recorded to date. It is associated with the high mortality of 50 per cent, the survival of the remainder being attributable to the existence of a very liberal system of collateral vessels and anastomoses throughout the entire course of the duct. In most instances rupture occurs on the right side, as the lower portion of the duct lies on this side of the body, being shielded on the left by the cushion of the aorta.

Clinical Features. On admission the patient is found to be suffering from shock, generally as a result of some injury to the back. He will gradually recover from the initial shock, and for a period varying from 2–6 days will appear to be progressing favourably, although hunger and thirst may be unduly pronounced. There are no characteristic early signs apart from those which are the direct outcome of the accident. At the end of a few days, however, there is nearly always a most dramatic change in his condition, and this usually coincides with the appearance of the chylothorax. The patient suddenly sinks back in bed in a semi-conscious state, gasping for breath and drenched in a profuse cold sweat. He may be pallid or slate-blue in colour, and lies motionless with half-closed glassy eyes. The pulse is racing, thready and weak, and the urine is scanty and loaded with acetone bodies.

On examination of the chest, signs of a pleural effusion, usually

affecting the right side, will be found. When this fluid is aspirated to relieve distress, its creamy character will at once proclaim the diagnosis. The frequent tappings of the chest and the withdrawal of large quantities of milky lymph will for a time add considerably to the comfort of the patient, and effect some improvement in his general condition. If, after a few days, the fluid continues to accumulate, the prognosis becomes exceedingly grave, and in the majority of cases hopeless. There will soon be marked progressive loss of weight, profound weakness, and insatiable thirst, all directly due to the lymphorrhœa. These cases become gradually worse and eventually die of exhaustion. If, on the other hand, the amount of pleural fluid which has to be withdrawn steadily decreases and the patient's general condition improves, it is clear that the flow of lymph is being diverted through other channels, that the breach in the thoracic duct is becoming closed, and that a normal flow of chyle is being re-established.

It will thus be found that in these cases of traumatic chylothorax it is often possible to recognise four distinct phases in the clinical picture: (1) The stage of *shock*, as a result of the accident; (2) The stage of *recovery* from shock—the latent period; (3) The stage of profound *collapse;* and (4) The stage of either *asthenia* and *inanition* leading to *death*, or of *recovery*. The latent period, i.e. the time which elapses between the initial injury and the onset of sudden collapse and pleural effusion—usually 2–6 days—is the most characteristic feature in the clinical history. It may be noted that before the fluid in the chest is aspirated, a provisional diagnosis of hæmatothorax is frequently made.

It is a remarkable and interesting fact that the effusion never occurs immediately after the injury. According to Macnab and Scarlett the abrupt onset and the gravity of the symptoms suggest a condition of anaphylactic shock. They write:

> "In our opinion the resemblance between this condition and that developing as the result of spontaneous pneumothorax is suggestive. One could account for the degree of shock on the basis of an abrupt disturbance of the pressure relations existing in the thoracic cavity with partial collapse of the lung due to the sudden release into the pleural space of chyle which previously had been protected in the parapleural tissues."

Prognosis. As already stated, in these cases the chances of recovery and of death are about equal. There are two causes of death:

(1) *Immediate*, due to suffocation and heart failure; and (2) *Remote*, the result of inanition through the loss of nutrient material normally carried to the subclavian vein by the thoracic duct.

(*b*) Operative wound:
(i) Duct completely severed.
(ii) One or more terminals cut.
(*c*) Gunshot wound.
(*d*) Stab wounds, self-inflicted or otherwise.

(2) *New Growths and Granulomata*, e.g. carcinomata, lymphosarcomata, or tuberculous mediastinal glands, producing obstruction of the duct by pressure from without and leading to rupture.

(3) *Thrombosis of the Left Subclavian Vein.*

(4) *New Growths of the Duct itself.*

(5) *Perforating Lymphangitis.*

(6) *Aneurysm of the Duct.*

(7) *Cirrhosis of the Liver.*

(8) *Filariasis.*

In a general way it may be stated that roughly half the cases of chylothorax result from spontaneous rupture of the thoracic duct following obstruction or compression by new growth or tuberculous disease of the mediastinal glands, and the other half from trauma.

TRAUMATIC CHYLOTHORAX

This is a rare condition, there being less than 100 cases recorded to date. It is associated with the high mortality of 50 per cent, the survival of the remainder being attributable to the existence of a very liberal system of collateral vessels and anastomoses throughout the entire course of the duct. In most instances rupture occurs on the right side, as the lower portion of the duct lies on this side of the body, being shielded on the left by the cushion of the aorta.

He will gradually recover from the initial shock, and for a period varying from 2–6 days will appear to be progressing favourably, although hunger and thirst may be unduly pronounced. There are no characteristic early signs apart from those which are the direct outcome of the accident. At the end of a few days, however, there is nearly always a most dramatic change in his condition, and this usually coincides with the appearance of the chylothorax. The patient suddenly sinks back in bed in a semi-conscious state, gasping for breath and drenched in a profuse cold sweat. He may be pallid or slate-blue in colour, and lies motionless with half-closed glassy eyes. The pulse is racing, thready and weak, and the urine is scanty and loaded with acetone bodies.

On examination of the chest, signs of a pleural effusion, usually

affecting the right side, will be found. When this fluid is aspirated to relieve distress, its creamy character will at once proclaim the diagnosis. The frequent tappings of the chest and the withdrawal of large quantities of milky lymph will for a time add considerably to the comfort of the patient, and effect some improvement in his general condition. If, after a few days, the fluid continues to accumulate, the prognosis becomes exceedingly grave, and in the majority of cases hopeless. There will soon be marked progressive loss of weight, profound weakness, and insatiable thirst, all directly due to the lymphorrhœa. These cases become gradually worse and eventually die of exhaustion. If, on the other hand, the amount of pleural fluid which has to be withdrawn steadily decreases and the patient's general condition improves, it is clear that the flow of lymph is being diverted *through other channels, that the breach in the thoracic duct is becoming* closed, and that a normal flow of chyle is being re-established.

It will thus be found that in these cases of traumatic chylothorax it is often possible to recognise four distinct phases in the clinical picture: (1) The stage of *shock*, as a result of the accident; (2) The stage of *recovery* from shock—the latent period; (3) The stage of profound *collapse;* and (4) The stage of either *asthenia* and *inanition* leading to *death*, or of *recovery*. The latent period, i.e. the time which elapses between the initial injury and the onset of sudden collapse and pleural effusion—usually 2–6 days—is the most characteristic feature in the clinical history. It may be noted that before the fluid in the chest is aspirated, a provisional diagnosis of hæmatothorax is frequently made.

It is a remarkable and interesting fact that the effusion never occurs immediately after the injury. According to Macnab and Scarlett the abrupt onset and the gravity of the symptoms suggest a condition of anaphylactic shock. They write:

> "In our opinion the resemblance between this condition and that developing as the result of spontaneous pneumothorax is suggestive. One could account for the degree of shock on the basis of an abrupt disturbance of the pressure relations existing in the thoracic cavity with partial collapse of the lung due to the sudden release into the pleural space of chyle which previously had been protected in the parapleural tissues."

Prognosis. As already stated, in these cases the chances of recovery and of death are about equal. There are two causes of death:

(1) *Immediate,* due to suffocation and heart failure; and (2) *Remote,* the result of inanition through the loss of nutrient material normally carried to the subclavian vein by the thoracic duct.

Treatment. This may be briefly outlined as follows:

(1) Treatment of shock and of any injury, e.g. fracture of the spine; (2) Repeated aspiration for the relief of distressing symptoms such as dyspnœa. Aspiration will usually be necessary twice a day owing to the large amount of fluid which rapidly accumulates in the chest; (3) A quantity of the aspirated chyle may be diluted and injected intravenously by the slow drip method in order to combat the rapid emaciation which accompanies the chylorrhœa, but this measure is of doubtful value; (4) Large quantities of fluid rich in carbohydrates should be given, but fats are forbidden; and (5) Thorocotomy is sometimes performed to create a continuous atmospheric pressure; it may also be indicated when aspiration would appear to be necessary more than two or three times a day in order to relieve the distressing symptoms of suffocation. If thorocotomy is performed, any clots or conglomerations of sticky gelatinous chyle must be removed at the same time.

The success of treatment depends almost entirely upon there being a sufficient number of collateral channels in the course of the duct in the thorax. If, happily, the collateral circulation at length becomes established, recovery of the patient is almost assured.

(C) *In the Abdomen*

The *causes of chylous ascites* and of retroperitoneal extravasation of chyle are similar to those already enumerated under chylothorax, and may be classified as follows:

(1) *Congenital,* e.g. distension and rupture of the thoracic duct proximal to a stricture.

(2) *Acquired:*

- (*a*) Trauma, such as may result from run-over accidents, fractures of the spine, acute hyperextension of the infant's trunk during parturition, gunshot wounds, stabs, or following excision of large retroperitoneal tumours, etc.
- (*b*) Rupture due to over-distension, as the result of compression or blockage of the duct by neoplastic tumours, tuberculous glands, or lymphadenomatous masses.
- (*c*) Diseases of the duct itself, e.g. cancer or aneurysm.
- (*d*) Filaria.
- (*e*) Secondary to cirrhosis of the liver, cardiac disease, nephritis, or amyloid disease.

Clinical Features. In the *congenital* cases difficulty in parturition may be experienced on account of the marked distension of the infant's

abdomen. Wegner, who has reported a case in which the baby presented a sorry spectacle, writes:

"He had the largest abdomen I have ever seen in an infant of his age. He made one think of a toy rubber balloon to which are attached a paper head and dangling paper arms and legs. The scrotum bulged irregularly and was so distended that the penis was buried by it. It contained fluid which was easily forced into the abdominal cavity. The abdominal walls were tense; the cavity was filled with *fluid. The enlargement was symmetrical. The intra-abdominal* pressure had forced the diaphragm upward, displacing the lungs and heart, and spreading the lower ribs. *Excepting the abnormalities described, and the fact that the child* was quite pale, he seemed to be normal."

In the *acquired* cases there is a gradually increasing distension following some injury to the lower portion of the spine or the abdomen,

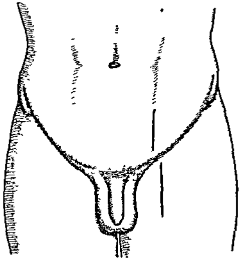

Fig. 2232.—Venous peritoneal anastomosis. Position of the incisions

or associated with some chronic intra-abdominal disease such as lymphadenoma. When the abdomen is tapped, the milky nature of the fluid will establish a diagnosis of chylous ascites. In certain cases it may be of academic interest to submit the ascitic fluid to cytological and chemical investigation in order to determine whether the condition present is one of true chylous or pseudo-chylous ascites (Quincke), but the findings will have no influence upon the method of treatment to be adopted.

On paracentesis, several pints or even gallons of chyle will be withdrawn from the abdomen, after which, in cases due to growth or granulomatous masses, tumours may be felt on examination of the abdomen. The fluid rapidly re-accumulates, re-distending the abdomen, bulging the flanks, and pushing up the diaphragm so that the heart's action is embarrassed and there is difficulty in breathing. Owing to the repeated tappings which are necessary to relieve this distension and the

patient's distress, there is progressive loss of weight, asthenia, dehydration, and pronounced and unquenchable thirst. Most of these cases will die of inanition, peritonitis, or some intercurrent disease such as pneumonia. Occasionally, however, and especially in those cases which are the result of trauma, spontaneous recovery may take place if the flow of chyle becomes re-established through the collateral channels.

Treatment. This depends upon the nature of the cause, but will usually comprise tapping the abdomen. Permanent drainage with a

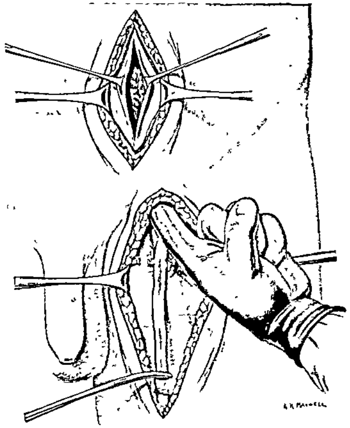

Fig 2233.—Venous peritoneal anastomosis. The vein has been freed, and the subcutaneous tunnel prepared. Through the upper incision the peritoneum has been opened so that chylous fluid may be withdrawn by suction prior to anastomosis.

Southey tube, and laparotomy followed by washing out the peritoneum, have been practised, but are of no permanent value. In congenital chylous ascites, however, or where the patient has received some injury from which he is slowly recovering but which has caused intraperitoneal rupture of the duct, the establishment of *venous peritoneal anastomosis* is well worth a trial. This is performed as follows: Assuming that the operation is being undertaken on the left side, a small low-placed vertical incision is made at the outer border of the left rectus muscle, all tissues being divided down to the parietal peritoneum, which is then picked up and incised for a distance of one

inch, each edge of the peritoneum then being clipped with a hæmostat. Another incision, commencing one inch below the inner third of the inguinal ligament and extending downwards for three inches or more on the antero-medial aspect of the left thigh, is made over the course of the internal saphenous vein (see fig. 2232). This vein is identified, isolated from the saphenous opening, and freed downwards for a distance of about three to three and a half inches, its tributaries being divided close to the vein and ligatured with fine plain catgut. The lowest

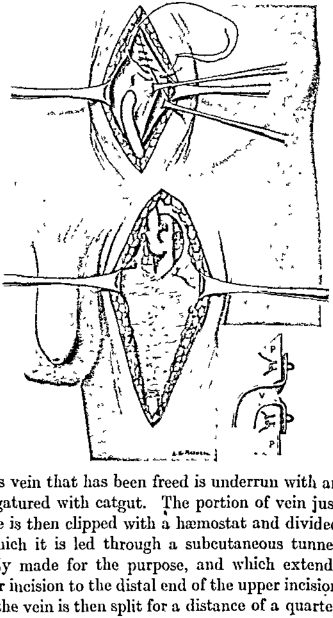

Fig 2234.—VENOUS PERITONEAL ANASTOMOSIS. THE OPERATION IS NEARLY COMPLETED, AND THE PARIETAL PERITONEUM IS BEING SUTURED.

(*Inset*) CROSS SECTION OF THE VEIN, SHOWING METHOD OF ANCHORING THE CUT EDGES OF THE VEIN TO THE PERITONEUM

portion of the saphenous vein that has been freed is underrun with an aneurysm needle and ligatured with catgut. The portion of vein just proximal to this ligature is then clipped with a hæmostat and divided with a scalpel, after which it is led through a subcutaneous tunnel which has been specially made for the purpose, and which extends from the top of the lower incision to the distal end of the upper incision (fig. 2233). The end of the vein is then split for a distance of a quarter of an inch and drawn through a small opening in the peritoneum medial to the original incision, and the two portions of the divided vein are stitched with fine catgut to the parietal peritoneum in the manner

depicted in figure 2234. Both parietal and femoral incisions are then closed in the usual manner.

The success of this operation, which may at times be spectacular, depends upon scrupulous attention to many minor but important points in technique. Thus, the portion of the saphenous vein selected must not be bruised or damaged in any way, either with the fingers or with instruments, during the process of freeing it from the thigh, as this will lead to endophlebitis with subsequent clotting and obliteration of the lumen of the vein; it must not be kinked at its point of junction with the femoral vein; there must be no undue tension or stretching of the segment of vein between its two points of attachment; chilling of the vein must be prevented by playing a jet of warm saline on it during the whole course of the operation; and, finally, the tunnel which is made in the subcutaneous tissues must be of dimensions adequate to accommodate the vein without unduly compressing it. If these precautions are observed, the operation should not infrequently prove successful.

INFLAMMATIONS OF THE LYMPHATIC VESSELS—LYMPHANGITIS

Infection of the lymph vessels may be acute or chronic.

(1) *Acute Lymphangitis.*

This is an acute inflammation of the lymphatic vessels due to infection with pyogenic micro-organisms, usually streptococci, although staphylococci or mixed infections or their toxins are sometimes responsible. The invading organisms usually gain entrance to the lymphatic vessels through pricks or abrasions in the skin or mucous membrane, or through small cuts, dirty contused wounds, infected sores, furuncles, etc. In a number of cases the primary breach in the skin is completely healed, covered by a scab, or difficult to identify, although at other times the focus of infection is obvious.

"Acute lymphangitis is characterised by a tenderness along the course of the main lymphatic trunks situated between the infected wound and the nearest group of lymph nodes. In severe cases a red line will be seen, in the case of the upper limb running along the front of the forearm and upper arm to terminate in the axilla. The red line may not, except perhaps in the most severe cases, be continuous, but only seen as an interrupted line and sometimes as a diffuse one. The actual cause of this lymphangitis is not clear. Infection may spread from the primary lesion to the lymphatic gland by an embolus, the lymphatic vessels themselves escaping disease, but in those cases where lymphangitis is present, inflammation of the walls of the lymphatic vessels must be due either to the presence of organisms actually growing in the lymphatic vessels or due to the irritation by exotoxins manufactured at the site of the primary lesion. It seems reasonable to suppose that the former is the case, the organisms growing along the main lymphatic trunks by a process of permeation similar to that of cancer cells,

differing, however, in the extreme speed with which pyogenic organisms multiply. This statement is borne out by the frequent occurrence of abscesses in the cellular tissue along the course of the main lymphatic trunk. The red line is, in fact, due to peri-lymphangitis or inflammation of the cellular tissue *in immediate contact* with the lymphatics. It is probable that when a red line is present, whether due to exotoxins carried by the lymphatic stream or to the actual presence of organisms growing along the lymphatics, the lymphatic vessel itself becomes occluded, and this adds to the inflammatory œdema which is a characteristic feature of the condition. Localised abscesses in the peri-lymphatic cellular tissue are due to leakage of the organisms from the lymphatic wall at a place where the inflammation due to their presence has destroyed it." (Harold Edwards.)

The effects of the infection naturally depend upon the virulence of the infecting agent and the resistance of the patient. The majority of cases rapidly respond to treatment, but a few may develop acute fulminating septicæmia, particularly patients who are very debilitated and those who are suffering from diabetes, chronic nephritis, or tuberculosis. General or constitutional disturbances may be absent or negligible, but where the disease is eager in its course the patient will complain of shivering attacks, a burning pain in the affected area profound depression, intense headache, anorexia, nausea and vomiting The danger signals are a rapidly mounting temperature, a running pulse, a flushed face with bright attentive eyes, dry parched lips and tongue, and excitable speech, together with a rapid spread of the local infection, leading in some cases to delirium, collapse, coma, and eventually to death.

Treatment. As every patient with acute lymphangitis may possibly develop septicæmia, a serious view must be taken of each individual case, and treatment be instituted at once on the following lines:

If the primary focus of infection is limited to a *small* circumscribed area, it may be ignored, excised or cauterised. If, however, there is an *extensive* septic area, it is best left severely alone after free painting with a strong antiseptic solution, such as tinct. metaphen (Abbott), or dressing with a reliable antiseptic ointment made up as follows:

Phenol	1 per cent.
Salicylic acid	2 per cent.
Camphor	3 per cent.
Pure lanoline to ½ oz.	

If a limb is affected it must be kept completely at rest, splinted and elevated, the most comfortable splint being of the gutter type made of plaster-of-Paris. If the lymphangitis is limited to a small area, say, to that of a finger or the dorsum of the hand, strapping firmly and evenly with elastoplast—the occlusive form of treatment—is well

worthy of a trial. Usually, however, large hot compresses of magnesium sulphate in glycerine (20 per cent) are applied, not only to the area immediately affected but to the part well above and below the lesion. These compresses should be changed frequently, and be covered with thick layers of gamgee tissue over which jaconet is placed, and the whole dressing lightly bandaged. A pad of antiphlogistine, $\frac{1}{4}$-inch thick and of appropriate size, is one of the best applications. Raised to a temperature as high as can be borne with comfort, it retains its heat for a considerable time and need not be changed more than twice a day.

Under no circumstances should incisions be made into areas of lymphangitis or subcutaneous cellulitis unless it is clear that there are definite local collections of pus which require to be evacuated. The making of multiple small incisions into an area of spreading infection in the skin is to be deprecated, as these incisions have no effect in arresting the progress of the disease, the drainage afforded is minimal, and the natural barriers to the infection may be broken down, leading to the entry of organisms into the general circulation.

As the invading organism is nearly always the streptococcus, *polyvalent anti-streptococcal serum and/or anti-scarlatina serum* should be injected. The initial dose of either of these sera should always be large. It is far better to inject a total amount of 50 cc. of polyvalent anti-streptococcal serum intramuscularly, or intravenously (but very slowly) diluted with one pint of normal saline, or 30 cc. of anti-scarlatina serum similarly diluted if given intravenously, than to give, say, 10 cc. daily for 5–6 days. Daily intravenous injections of hydrarg. perchlor., $\frac{1}{32}$–$\frac{1}{16}$ gr., of arsenic in the form of N.A.B., or of mercurochrome for two to four doses may be tried, but in my experience they have not proved to be of much value in cases of frank septicæmia. During recent months prontosil (Bayer) has been extensively used in the treatment of streptococcal infections, and, on the whole, the results obtained appear to be encouraging. This substance is available in three forms: (1) Prontosil soluble (for injection); (2) prontosil red tablets; and (3) prontosil album (the sulphonamide preparation). All are closely interrelated chemically, the first two being azo dye compounds. They have *in vivo* action against hæmolytic streptococcal, and possibly other, infections not yet fully explained. Reference to their clinical use may be found in the articles by Leonard Colebrook and others in the *Lancet* of June 6th, 1936, and elsewhere. According to the severity of the condition, the patient should receive daily intramuscular injections of up to 40 cc. (in exceptionally severe cases more) spread over twenty-four hours. The injections are continued

until the temperature falls and the pulse-rate approaches normal Treatment may conveniently be continued with tablets, 1–2 well chewed up and taken with plenty of fluid three times a day, for 4–5 days after the temperature has fallen to normal. The prontosil red tablets, which were originally used in Dr. Colebrook's work, may be replaced by prontosil album, which is non-staining. At present, however, clinical evidence is not available to enable us to say which of these two oral drugs is the more satisfactory. Cyanosis may follow the use of prontosil in cases of renal or hepatic insufficiency.

In grave cases the patient should be ordered large quantities of fluids, i.e. 6–10 pints each day, and in certain instances this should be supplemented by intravenous or rectal salines. An easily assimilated diet rich in vitamins and sugar is also prescribed.

When the acute affection has subsided, the anæmia which may result may be counteracted by means of adequate doses of ferri et ammon. cit., e.g. 30–45 grs. t.d.s., and the healing of the drainage wound (if any) accelerated by a course of artificial sunlight. Radiostoleum or some similar concentrated vitamin preparation may be given during the acute stages, and may be continued during the period of convalescence. When healing has occurred, it is essential that the patient should be sent away for convalescence before resuming work.

(2) *Chronic Lymphangitis.*

Chronic simple (pyogenic) lymphangitis is commonly a sequel to an acute attack. In such cases the lymphatic vessels may feel like long thin cords running under the skin. There may also be an associated œdema of the affected part.

Syphilitic lymphangitis is well seen in cases of Hunterian chancre, where the indurated lymphatic strands can be seen and felt travelling from the sore on the penis to the enlarged, shotty inguinal glands.

Tuberculous lymphangitis is occasionally seen in association with tuberculous ulcers of the skin. The infection spreads along the lymphatic vessels which become hard, swollen, beaded, and somewhat tender. The nodules which form here and there in the line of the involved lymphatics may soften, break down, and discharge thin pus, giving rise to a chronic ulcer which has undermined edges and a base lined with pale pink watery granulation tissue. The skin surrounding these ulcers is often involved in the infection, and presents a shiny purple- or mauve-coloured appearance. Very often wide excision with the cautery is the only successful treatment for such cases.

INNOCENT NEW GROWTHS OF THE LYMPHATIC VESSELS—LYMPHANGIOMATA

These tumours somewhat resemble hæmangiomata, except that their channels and spaces contain lymph instead of blood. They are believed to be congenital in origin and to arise in defects in the development of the lymphatic vascular system.

Lymphangiectasis is a term applied to those cases in which the lymphatic vessels become dilated following injury or inflammation, and where their continuity with the normal lymphatic circulation persists. A lymphangioma, on the other hand, is the result of a new formation. Sometimes the two conditions develop side by side. There are three varieties of lymphangioma: (1) Capillary or nævoid; (2) Cavernous; and (3) Cystic hygroma.

Capillary or Nævoid Lymphangiomata. These are usually small, pink or yellowish-brown, cystic, circumscribed swellings, and are in many respects similar to the nævi which occur on the skin and mucous membrane. In certain cases, however, they may be diffuse, as, for instance, in the tongue (see page 3018). These lymphatic tumours are most frequently seen on the lips (*macrocheilia*), cheeks, tongue (*macroglossia*), skin, subcutaneous tissues, in or between muscles, in the viscera, etc. In some instances there may be a combination of lymphangiomatous and hæmangiomatous tissues in a single tumour. Histologically, they are composed of a complicated system of anastomosing channels or spaces, lined by flattened or cubical endothelium and filled with clear limpid fluid containing a few lymphocytes. The supporting stroma is composed of fibro-fatty tissue. If small, the tumours should be treated by excision or cauterisation. If diffuse, they are often resistant to treatment and tend to ulcerate and produce a great deal of pain. Cure may sometimes be effected by means of radium, X-rays, or electrolysis.

Cavernous Lymphangiomata. These innocent endothelial growths closely resemble cavernous nævi, and usually affect the subcutaneous tissues, the mucous membrane, the prepuce, or the intermuscular septa, their treatment being in every respect similar to that of cavernous nævi.

Cystic Hygromata. These are rare tumours, generally seen before the age of 10, although adult cases have been reported. Herzfeld considers that they are the commonest lesion observed *at birth.* They are probably sequestrations of lymphatic tissue (due to some developmental fault) which have maintained the power of persistent but irregular growth. Those that occur in the neck usually

have their origin in the vestigial rests of the large jugular sacs. They are mostly amalgamations of multilocular, thin-walled cysts, lined with a single layer of endothelium having the appearance of a mosaic, contain clear serous fluid, and possess a remarkable power of growth. The following is the order of frequency in which they appear in different parts of the body: the neck, the axilla, the pectoral region, the sacral region, the retroperitoneal tissues, the great omentum, between the layers of the mesosigmoid, the groin, the floor of the mouth, the liver, and the suprarenal gland.

When occurring in the *neck*, such a tumour usually arises under the sterno-mastoid muscle as a multilocular cystic swelling which protrudes into the anterior and posterior triangles and sometimes extends underneath the clavicle and downwards into the axilla. The individual cysts, surrounded by a supporting framework of fibro-fatty tissue which binds them together, are also adherent to neighbouring muscles, to vascular sheaths, to large nerves, and even to the skin when following an inflammatory attack.

In certain instances the tumours may be unilocular, when they are termed *solitary lymphatic cysts*. These cysts, which also are thin-walled, lined with a single layer of flattened endothelium, and which contain clear limpid fluid, are chiefly found in the neck where they are seen as smooth, fluctuating, elastic, slow-growing, globular swellings. They may lie behind the belly of the sterno-mastoid muscle or in the posterior triangle of the neck above the clavicle. *Cystic lymphangiomata of the mesentery* are undoubtedly among the rarest tumours encountered in the field of general surgery. Parsons was able to find approximately 500 cases of mesenteric cysts, but only 10 true lymphangiomata, and he has contributed to the literature a detailed report of a case which occurred in his practice, together with a full bibliography of the condition (*Ann. Surg.*, April 1936, 520, 595).

A *cystic hygroma in the neck* must be distinguished from: (1) Lipoma; (2) branchial cyst; (3) aberrant lateral adenoma of the thyroid; (4) angiosarcoma; (5) aneurysm; and (6) tuberculous abscess.

Treatment. In view of the tendency to spontaneous recession which all these tumours possess, surgical treatment is never called for immediately. The *solitary cysts* should either be excised, or their contents aspirated and the cyst cavity injected with 3–5 cc. of quinine-urethane or lithocaine to effect cure by a process of slow fibrosis and cohesion of the walls of the cyst. The *multilocular cysts* are exceedingly difficult to excise completely, as they are so firmly adherent to important

structures in the neck, such as the large vessels and nerve trunks. If small and easily accessible, they should be dissected out; but if large and deeply penetrating, treatment by means of X-rays or radium is to be preferred to a partial removal of the tumour, as dangerous septic complications may follow the latter attempt. In those cases where at operation it is found impossible to dissect completely the whole of the ramification of the cyst-like processes which have extended far beyond the operation area, the wound should be closed, drainage instituted, and, when healing is nearly established, the parts should be subjected to a course of X-ray treatment.

As an alternative to X-ray or radium treatment in cases where excision is impossible, Harrower's method of repeated injection of the cystic mass with sodium morrhuate may be recommended.

CHAPTER II

Inflammation of the Lymphatic Glands—Lymphadenitis

by

Rodney Maingot

(A) Acute Lymphadenitis.
(B) Chronic Lymphadenitis:
(1) Simple; (2) Syphilitic; (3) Tuberculous.

ACUTE LYMPHADENITIS

Acute lymphadenitis is inflammation of the lymphatic glands caused by organisms reaching them via the lymphatic vessels from the skin or mucous membrane. The infecting organism is usually pyogenic, but at times B. mallei, B. anthrax, B. pestis, or Ducrey's bacillus may be responsible.

In all cases the area which drains into the lymphatic glands should be very carefully examined for cuts, scabs, sores, infected blebs, etc. The glands are enlarged, elastic, painful and congested, later becoming adherent to one another and to neighbouring tissues, while the overlying skin is often œdematous and red. As the glands enlarge in size they form one indefinite confluent tumour. With removal or with appropriate treatment of the primary focus of infection and local treatment of the affected glands, resolution will frequently occur. Failing this, the glands may become chronically infected and enlarged, in which case —particularly when those in the neck are concerned—the tubercle bacillus is likely to become an additional infecting agent. On the other hand, the glands may soften and suppurate, forming a large abscess which may spread widely in the surrounding tissues or discharge on to the surface. The common symptoms of toxæmia, such as malaise, fever, lack of appetite, etc., may or may not be present. In certain instances the general disturbance may be very marked, suggesting that the infecting organisms have entered the blood stream giving rise to a widespread septicæmia.

The different groups of glands which are most commonly infected are the following: (1) The superficial glands of the head and neck;

(2) the deep cervical glands; (3) the lateral pharyngeal glands; (4) the glands of the upper extremity, sub-divided into the epitrochlear, and the axillary and pectoral groups; (5) the glands of the lower extremity—the popliteal, the inguinal, and the iliac; and (6) the abdominal glands.

The methods of dealing with all acutely infected superficial glands, such as those that may occur in the neck, are in the main similar, and may be briefly outlined as follows:

(1) *Local Treatment.* This consists of attacking, if possible, the primary focus of infection and applying frequent fomentations or antiphlogistine to the affected area until resolution has taken place, or until an abscess has formed and is pointing. This can then be drained through a small judicious incision. Subsequently, a small tube is inserted into the abscess-cavity for the purpose of drainage. After this, hot hypertonic saline (15 per cent) dressings should be used, as it is not advisable to apply antiphlogistine to open wounds. In those cases in which the glands remain enlarged and show no signs of subsiding or of suppurating, it may be well to dissect them out completely, after which the wound is partially closed and drained.

(2) *General Treatment.* The patient is put to bed, and the affected part is splinted or otherwise immobilised as completely as possible. The bowels are made to act by means of saline aperients, fluids are given in abundance, and a diet of ample vitamin content is prescribed.

(3) *Treatment of Suppurating Lymphatic Glands.* This is best considered on a regional basis. A detailed description under five headings is given below:

(*a*) *Uncomplicated Cervical Abscesses.* These abscesses are nearly always secondary to some local infection in the skin, such as a boil in the neck or face, but occasionally they may result from infection from the lips, tonsils or gums. In dealing with such cases it is best to delay operation until the centre of the swelling is soft or until the overlying skin becomes œdematous. A small incision is made over the most prominent part of the swelling, a pair of sinus forceps is thrust into the abscess-cavity, a tube is inserted (and fixed into position with a single stitch), and fomentations are then applied four-hourly. The three conditions which most closely simulate an acute cervical abscess are: (i) infected branchial cyst; (ii) infected cystic hygroma; and (iii) infected thyroglossal cyst.

(*b*) *Submaxillary Glands.* Suppuration is comparatively common in this site, and frequently results from an infected tooth socket. The enlarged glands form a tumour in the region of the submaxillary salivary gland which, with the aid of fomentations, will slowly soften and break through the deep cervical fascia to present a fluctuating swelling. As soon as this is detected, it should be evacuated by Hilton's method. There is no danger of damaging the facial artery provided the incision is a small one and is made over the point of maximum swelling. A

drainage-tube is passed into the wound and stitched to the edges of the skin. This tube is removed in two or three days, after which rapid healing takes place.

(c) *Axillary Abscess.* An abscess in the axilla must be opened and drained without delay, as the pus tends to travel along the path of the nerve trunks into the neck. The site of the incision depends upon the spot at which the abscess points, but as in the average case the abscess lies under the pectoralis major it is best to make an incision about two inches long, just below the fold of this muscle in its upper part. Through this incision a pair of sinus forceps or a hæmostat is thrust upwards and inwards, and the blades are gently opened. A finger inserted through the incision breaks down any loculi in the abscess-cavity. Drainage is provided. In certain cases of long-standing inflammatory enlargement of the glands lying under the pectoralis major, associated with marked constitutional symptoms and failing to subside under prolonged local treatment, it is often advisable to cut down upon and remove the glands through an incision placed just below the fold of the muscle.

(d) *Abscess in the Groin.* This is nearly always secondary to infection of the genitalia, of the anal region, or of an area of skin in the lower extremity (commonly the foot), and should be opened by a vertical incision. Where acutely infected glands in the inguinal region, as elsewhere, show no signs either of resolution or of frank suppuration after a thorough course of local treatment, they should be dissected out, and after every bleeding point has been ligated, the wound should be lightly smeared with B.I.P.P. and partially closed (with drainage).

(e) *Suppuration of the External Iliac Glands.* These receive the efferent lymphatics from the inguinal group of glands which normally drain the lower limb, genitals and perineum, and occasionally become infected without there being much evidence of the superficial or sub-inguinal group being first involved. When they are extensively diseased they may form a large tender mass above the inguinal ligament, which, when on the right side, may closely simulate an appendix abscess, and when on the left, an abscess in connection with a perforated diverticulum of the sigmoid colon. In the female, inflammation of these glands may resemble a severe case of parametritis. When suppuration is extensive, a tender mass may be made out above or below the inguinal ligament, associated with considerable fixation and induration. These cases should be put to bed, and, after treatment has been directed to the primary source of the infection, fomentations should be applied frequently over the affected area until an abscess forms, when this should be opened through a small incision made just above the anterior superior iliac spine, care being taken to avoid opening the peritoneal cavity. Where the inflammatory mass shows no signs of subsiding after an adequate course of treatment, it is often best to cut down on the glands, expose them extraperitoneally, and dissect them out completely. The wound is then partially closed, and drainage instituted.

ACUTE ABDOMINAL LYMPHADENITIS

This condition is due to infection of the abdominal lymphatic glands by pyogenic organisms, the infection reaching them from the gut via the lymphatic vessels. It is conceivable, however, that in certain cases the lymph nodes become infected through the blood stream.

Rendle Short in a series of 200 laparotomies was able to determine its incidence at 6 per cent. Acute abdominal lymphadenitis occurs chiefly before the age of 15, and affects the two sexes with equal frequency.

The *signs and symptoms* of this disease in its *acute* form simulate those of acute appendicitis so closely that the two conditions cannot easily be differentiated. The pain usually commences in the region of the umbilicus or epigastrium, and is often accompanied by colicky spasms; the temperature varies from 99°-104° F., and there is a moderately accelerated pulse-rate. There is often nausea, and the patient may vomit once or twice, but vomiting is, as a rule, not a common symptom. The pain eventually settles down in the right iliac fossa or hypogastrium, and is of a dull gnawing or continuous aching character. At other times, however, it ceases as suddenly as it began, only to recur at intervals with equal intensity. On *examination*, a definite area of abdominal tenderness, cutaneous hyperæsthesia, slight muscular spasm, and rigidity can sometimes be made out in the right iliac fossa, usually over McBurney's point. As a rule, no masses are felt, and a rectal examination is negative. A blood count will frequently show a leucocytosis of 12,000 to 18,000 per cubic mm., 80 per cent of the cells being polymorphonuclear.

There is a *chronic* form of the disease in which the patient gives a long history of loss of energy and of weight, and of recurrent short spells of abdominal distress, each culminating in an attack of acute abdominal pain which may last for a few hours or subside with dramatic abruptness, only to return after a brief interval.

The mechanism of the infection is unknown, but one may assume that the portals of entry for the micro-organisms are located in an area of catarrh or in a minute ulcerated patch in the mucous membrane of the lower ileum, cæcum, or appendix. Contaminated food or milk may be a vehicle of infection, whilst intestinal parasites and local trauma of the gut may be predisposing factors.

The following have to be considered in the *differential diagnosis* of the *acute* type: (1) Acute appendicitis; (2) tuberculous mesenteric lymphadenitis; (3) intussusception; (4) inflammation of Meckel's diverticulum; (5) acute pyelonephritis; and (6) acute regional ileitis (Crohn, Ginsburg and Oppenheimer, 1932, *J.A.M.A.*, Vol. 99, 1323).

Treatment. As the condition in its acute form cannot otherwise be distinguished with certainty from acute appendicitis, exploratory laparotomy should be undertaken without delay, and the appendix should in all cases be removed, whether it appears to be diseased or

normal. The manifold enlarged glands, elastic, discrete, swollen, and usually found at the root of the mesentery, along the course of the ileo-colic artery, and in the ileo-cæcal angle, *should not be disturbed*, although it is advisable to remove an easily accessible gland for biopsy. Free peritoneal fluid, which is usually present in excess, should be mopped up or removed by suction.

The *prognosis* following laparotomy and removal of the appendix is very good, and in the majority of cases a complete recovery may be expected in due course. Strömbeck followed up 40 cases which had been operated upon over four years previously, and found that 87 per cent were free from symptoms. He had no operative deaths in his series, and similar satisfactory results are reported by Rendle Short and others.

CHRONIC LYMPHADENITIS

(1) *Chronic Simple Lymphadenitis.*

This condition, which is often mistaken for tuberculous lymphadenitis, is due to an infection of the lymphatic glands with pyogenic micro-organisms. When occurring in the neck it is almost always due to a persistent primary focus of infection in the area drained by the glands. The commonest causes are: (*a*) Oral sepsis (carious teeth, gingivitis, alveolar periostitis, chronic tonsillitis, chronic pharyngitis, etc.); (*b*) lesions of the skin or scalp (eczema, impetigo, pediculosis of the scalp, ulcers, cuts, cracks, fissures, etc.); and (*c*) a preceding acute septic adenitis. Occasionally the infection is hæmatogenous and may occur as a complication of some acute infectious disease. When the glands in the axilla or groin become chronically infected, the primary focus can nearly always be found in the form of infected cuts, ulcers, etc., in the hands, feet, or genital area. Clinically it is often impossible to distinguish the condition from tuberculous lymphadenitis or lymphadenoma, and unless a cure is quickly effected after removing the focus of infection, it may be advisable to remove one of the enlarged glands and submit it to microscopical examination before making a final diagnosis. The glands in chronic simple lymphadenitis are tender, moderately enlarged, rounded, smooth, elastic, firm, and movable under the skin. When peri-adenitis occurs, fixation results, and tuberculosis becomes almost impossible to exclude clinically.

As stated above, treatment consists in removal of or other attention to the primary focus of infection, local applications of heat or counter-irritants to the affected glands, and general tonic treatment. If after a period of, say, three months the glands still persist and show no signs of subsiding, although the primary lesion has resolved

satisfactorily, they should be regarded as tuberculous unless biopsy proves the contrary.

(2) *Syphilitic Lymphadenitis.*

The lymphatic glands become infected in cases of primary syphilis. In cases of genital chancre the glands are discrete, hard and shotty, whereas with extra-genital chancres, such as may occur on the lip, breast, etc., they are usually larger, softer, acutely inflamed and inextricably matted together. In the genital type suppuration does not occur unless secondary infection is superimposed. In secondary syphilis there is usually a general sub-acute adenitis. Tertiary syphilitic lesions of the lymphatic glands are extremely rare, but when they occur they closely resemble "breaking-down" tuberculous glands, in that there is a matting together and softening of the lymph nodes, this being followed by a discharge of grumous material through single or multiple sinuses in the skin. Gummatous adenitis is more often seen in cases of inherited syphilis than in the acquired type. The *treatment* of this condition is discussed under Syphilis (see page 5317).

(3) *Tuberculous Lymphadenitis.*

(*a*) *Ætiology.*

(i) *Age and Sex.* Tuberculous disease of the lymphatic glands may occur at any age, although the majority of cases are seen in children. Females are said to be more frequently infected than males.

(ii) *Heredity.* As far as can be ascertained, there does not appear to be any evidence that the disease is hereditary, but there is no doubt that children of tuberculous parents are more prone to develop it. A clear history of contact with an infected adult is sometimes obtainable.

(iii) *Incidence.* There appear to be a number of reasons why tuberculous lymphadenitis is a disease which is fast decreasing in frequency: 1. The testing and gradual elimination of cows infected with tuberculous disease; 2. the effective pasteurisation of milk; 3. the modern tendency to remove tonsils and adenoids from children of school age, and to treat all septic foci promptly; 4. the isolation of patients, both adults and children, suffering from active phthisis; 5. the existence, nowadays, of better methods of hygiene and a higher standard of living, together with a more careful medical supervision of children by means of clinics, etc.; and 6. the increased resistance of the general population to the disease. This is probably the result of some important but little understood biological phenomenon, but may be in part explained by the prominence now given to a universal and well-organised campaign against the disease.

(*b*) *Bacteriology.*

Like other forms of non-pulmonary tuberculosis, tuberculous lymphadenitis is, in most instances, caused by the bovine type of bacillus, and this is especially the case in children. It is found that the older the patient the more likely he is to become infected by the human rather than by the bovine type; but in both infections the clinical features, the pathological changes in the involved tissues, and the treatment to be adopted are alike.

(*c*) *Pathology.*

The process of the infection and its results may be briefly outlined as follows: The tubercle bacillus travels to the glands by one of two routes—the lymphatic vessels or the blood stream. The bacilli are deposited in a lymphatic gland and light up an irritative and reactionary inflammatory process, with the formation of tubercles or tuberculous follicles. If the disease is overcome, resolution occurs with the production of scar tissue which envelops or replaces the lesion and its causative bacilli. It always leaves its impression upon the gland, however, in the form of fibrous tissue, and in some instances depositions of chalk. When, on the other hand, the disease progresses, caseation takes place, often leading to liquefaction and tuberculous abscess formation, with spread of the infection to other tissues.

The *macroscopical* appearances of a tuberculous gland in the various stages of the infection are usually characteristic. Thus, early in the disease the gland is pale, fleshy, uniformly enlarged, and elastic, while on section no tubercles may at first be made out. Later on, small white or yellow spots, which represent tubercles, will be seen scattered over the surface of the cut gland. At an even later stage, small, discrete, caseous areas may be detected in different portions of the gland. These eventually coalesce until the whole or the greater part is replaced by cheesy material. The capsule of the gland becomes greatly thickened by the fibrous tissue resulting from the inflammation. When the peri-glandular connective tissue becomes involved—peri-adenitis—the glands become adherent to one another and form large ill-defined masses; but when suppuration ensues there is abscess formation and the capsule of the gland may rupture, the contained creamy pus burrowing widely in various directions—along the nerve sheaths, the muscles, and the fascial planes. On the other hand, a local abscess may form, and this, according to its situation, may burst externally on to the skin surface, giving rise to a tuberculous sinus, or into a portion of the gut, into the peritoneal cavity, into a bronchus, etc.

Microscopically, the characteristic lesion is the tubercle, in the centre

of which tubercle bacilli in various stages of degeneration may be seen lying surrounded by endothelial and giant cells (fig. 2235). A little further afield there is an encircling zone of lymphocytes. The endothelial cells themselves are irregular and variable in shape—round, oval, or spindle-shaped—having clear cytoplasm with eccentric, pale-staining nuclei. They are probably derived from the endothelium of the blood-vessels and lymphatic vessels, and also from the fixed connective tissue cells of the part involved. The lymphocytes which occur at the periphery of the follicle are carried there by the blood stream; but in a lymphatic gland which is the seat of tuberculous

Fig. 2235.—MICROSCOPICAL SECTION OF A TUBERCULOUS GLAND.

disease they are probably also derived from the germ centres of the lymph follicles. The giant cells are large and somewhat irregular in shape, with ill-defined margins, and contain near their periphery numerous small, oval or circular nuclei, often arranged in the shape of a horseshoe.

(*d*) *Pathogenesis.*

The effect of the invading tubercle bacilli upon the lymphatic glands depends upon several factors. These are: (i) the virulence of the infection; (ii) the age, nationality, and resisting power of the patient: (iii) the presence or absence of superimposed pyogenic infection; (iv) the particular area affected by the disease; and (v) whether or not the patient contracted the disease in childhood—a fact which will considerably influence the course of a second infection in later life, for if there has been an attack in childhood, the

second infection tends, as a rule, to be milder and more chronic. The disease is commoner among the white than among the coloured races, but when it occurs in the latter it tends to be more lethal. Superimposed infection with pyogenic organisms is greatly to be feared, as it encourages dissemination of the tubercle bacilli and a more active local spread of the disease, abscess formation, marked constitutional symptoms, and other complications, such as the production of fistulæ.

The most important groups of lymphatic glands which may become involved in tuberculosis are: (i) the *cervical*; (ii) the *tracheo-bronchial*; (iii) the *axillary*; (iv) the *inguinal*; and (v) the *abdominal*. An account of the disease as it occurs in each of these groups will now be given.

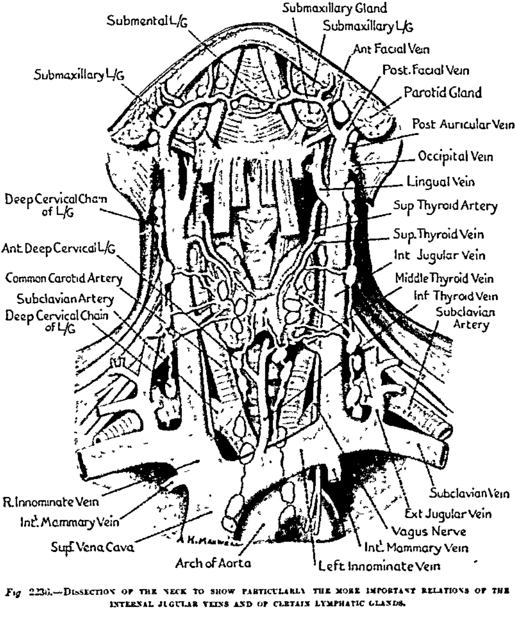

Fig 2236.—Dissection of the neck to show particularly the more important relations of the internal jugular veins and of certain lymphatic glands.

(A) *Tuberculous Glands in the Neck*

Reference to figures 2236, 2277 and 2719 will serve to remind the reader of some of the more important structures and their anatomical relations in the neck, mainly in so far as they concern certain operations for tuberculous lymphadenitis.

The lymphatic glands in the neck are arranged in systems, an upper and a lower circular system, and a vertical system. The majority of the glands in the circular system are superficial, whereas most of those in the vertical system are deep. The upper circular chain surrounds the base of the skull and drains chiefly the face and scalp, the glands in the chain intercommunicating in such a manner that they can pass infection from one gland to another. The groups of glands *in the upper circular system comprise the following:* the submental, the sublingual, the submaxillary, the supra-mandibular or facial, the parotid, the pre-auricular, the mastoid or post-auricular, the occipital, and the retro-pharyngeal. The lower circular chain is poorly represented, there being only a few glands sparsely scattered in the posterior triangle of the neck above the clavicle and in the supra-sternal region.

The vertical system of glands consists of a superficial chain and a deep chain. The chains of superficial glands lie beneath the deep fascia and follow the course of the anterior and external jugular veins. The deep glands, which lie mainly under cover of the sterno-mastoid, are divided on each side of the neck into an upper and a lower group by the line of the omo-hyoid muscle, each of these groups being sub-divided into an anterior and a posterior group. The glands of the upper deep cervical group, and especially those of the anterior division in this group (which are the most important and most frequently infected in the neck) include the *tonsillar or jugulo-digastric gland of Wood. These glands drain the tonsil, the* naso-pharynx, and the greater part of the mouth, and receive efferents from all the glands in the upper circular system. The tonsillar gland is usually constant in position and occupies the triangle formed by the posterior belly of the digastric muscle and the common facial and internal jugular veins. The upper posterior group of deep cervical glands lies behind the internal jugular vein, upon the splenius cervicis and levator scapulæ muscles. The spinal accessory nerve traverses these glands *in its downward course towards the posterior triangle of the neck.* The number of glands in the upper deep cervical group varies from 15–30 nodes. The retro-pharyngeal glands are situated behind the mucous membrane of the posterior wall of the naso-pharynx and anterior to the bodies of the cervical vertebræ. They drain into the upper deep cervical group.

The general flow of lymph in the neck is in a downward direction towards the jugular lymphatic trunks, which empty on the right side into the subclavian vein and on the left side into the thoracic duct. Reference to the Table on page 4125 will show clearly the arrangement of the lymphatic glands in the neck, according as they are grouped under the various systems.

Etiology. As has been stated earlier, the *incidence* of tuberculous glands in the neck is rapidly decreasing for the reasons already detailed. Whereas twenty years ago the removal of tuberculous glands in

the neck figured largely on the operation lists of almost every hospital, such dissections are now becoming more rare every year, owing to the fact that more cases are being treated by conservative methods and also to the fact that the disease itself is less common. One instance of this may be cited by a reference to the operation records of the Belgrave Hospital for Children where, according to Wakeley, there were 240 operations performed for tuberculous glands in the neck between the years of 1909 and 1913, and only 18 between 1929 and 1933.

Tuberculous glands in the neck are most common during the first decade of life, 50 per cent of cases occurring between the ages of 1 and 10. According to John Fraser, this age period is one in which the child is liable to come into contact with tubercle bacilli through the medium of infected milk; at the same time, the lymphatic system is profuse, highly active in its absorptive function, and yet only partially educated in the properties of resistance. Handford of America gives the following table:

AGE PERIOD.	PERCENTAGE OF INCIDENCE.
1–10	40 per cent.
10–20	35 per cent.
20–30	20 per cent.
over 30	5 per cent.

Most observers are agreed that the incidence is slightly more common in females.

Amongst the predisposing factors may be included any conditions which lower the general health. These may be repeated attacks of

tonsillitis: the exanthematous diseases, particularly measles, whooping-cough and scarlet fever: oral sepsis, especially carious teeth; chronic pharyngitis; repeated attacks of chronic simple (non-specific) adenitis; chronic otorrhœa associated with middle ear disease; and a number of other conditions, such as eczema of the face, impetigo, pediculosis, sores, cracks, fissures, abrasions, etc., of the face, scalp or neck. In cases of primary tuberculous disease of the tongue, larynx, lung, etc., there may be a *secondary* tuberculous lymphadenitis involving the glands of the neck. As previously stated, the bovine infection—infection by milk—predominates in children, but with increasing age infection with the human strain becomes more common.

The chief routes through which the human organism becomes infected with tubercle bacilli are: (1) the pharynx, and especially the tonsils and adenoids; (2) the mucous membrane of the bronchial tree; (3) the mucous membrane of the last foot or two of the ileum; and rarely (4) the skin. The tubercle bacilli penetrate the mucous membrane, usually without leaving any obvious lesion, and become transferred to the nearest lymphatic glands. Here they may remain and become imprisoned, or they may enter the venous circulation and so be carried to the lungs. Deposited in the lung parenchyma they may light up an infective process, or they may be sifted through the pulmonary tissue and then become lodged in the tracheo-bronchial glands, causing disease there. Alternatively, some of them may pass into the pulmonary veins and thence to the left heart, to be disseminated far and wide throughout the body by the arterial circulation. In the majority of cases of tuberculous glands in the neck, however, the infection is a local one, the bacilli gaining entrance to the lymphatics through the tonsils or the adenoid tissues of the naso-pharynx, or from the gums. Where the infection is blood-borne the enlarged glands are irregularly distributed, and there are, as a rule, constitutional symptoms.

Diagnosis. This may be simple, difficult, or even impossible unless a gland has been excised and submitted to microscopical investigation. Diagnosis is based on the following:

(1) The history of the case.
(2) The examination of the patient: (*a*) local; (*b*) general.
(3) Special examination: (*a*) complete blood count; (*b*) Wassermann reaction; (*c*) X-ray examination of the neck, lungs and abdomen.
(4) Aspiration and microscopical examination of the fluid withdrawn from an abscess.
(5) Biopsy of the enlarged glands.
(6) Guinea-pig inoculation.
(7) Tuberculin test.

In taking a history, inquiry will have to be made as to any recent illnesses, especially sore throats, etc., and whether or not there is any tuberculous disease in the family. Other details may also need to be investigated, such as the conditions under which the patient lives, the milk supply, etc., when the lump was first noticed, where it started, and whether or not it has progressively increased in size. In most cases there is a history of some long-standing cervical glandular swelling which is gradually enlarging, or the formation of an abscess which has burst, leaving a discharging sinus in the neck. As septic infection predisposes the lymphatic glands to an attack by the tubercle bacillus, a careful search must be made for any focus of infection, and special attention must be paid to the area drained by the glands. The scalp should be examined for any evidence of sores or pediculi, the face for infected pimples, cuts, etc., and the teeth, tonsils and pharynx for any signs of infection. The tonsil is recognised to be the most important focus of infection. Barrington-Ward, for instance, found that the tonsillar gland was the one chiefly affected in 97 out of 161 cases, and that in 43 other cases the glands in the anterior triangle were diseased, the probability being that the tonsil was the seat of infection.

The tumour in the neck should be carefully examined, and the following points noted: its size, shape, position and consistency; the condition of the overlying skin; any evidence of sinuses; and whether or not there is any sign of matting. Search should also be made for enlarged glands in other parts of the body, such as the axilla, groin, etc., and the investigation completed by an examination of the chest and abdomen. It should be remembered that, with the exception of pyogenic infection, tuberculosis is the commonest cause of enlarged cervical glands, and the diagnosis should be in little doubt if the glands become progressively and painlessly enlarged in spite of appropriate treatment. Pain is always present in cases of peri-adenitis or caseation. In the average case, a firm, elastic, somewhat movable, elongated swelling will be detected in the neck (usually not tender on palpation), and smaller discrete nodes may be made out nearby. When caseation takes place the glands become boggy, and later a fluctuating, ill-defined mass, or a definite abscess, will be found. In neglected cases such an abscess may accumulate under the skin, burst, and discharge watery pus containing solid yellow flakes of necrotic tissue. There may also be evidence of toxic absorption, the patient being pale and languid, and suffering from evening rise of temperature with night sweats, lack of appetite, and loss of weight.

Tuberculous disease may be diagnosed if, after the removal of any obvious source of sepsis, the glands continue to enlarge, or do not disappear after a period of, say, three months; if they show any alteration in consistency—i.e. becoming softer; or if, should an abscess form, the aspirated material presents the features usually associated with tuberculous pus.

The main difficulties in diagnosis concern the really early stages of the disease, when only one or two discrete enlarged glands can be felt, and a later phase, when cold abscess formation is associated with thinning and reddening of the overlying skin. In the former case, if an *immediate diagnosis is imperative, a biopsy will be necessary*, whereas

Fig 2237.—Tuberculous abscess in the neck due to a breaking-down lymphatic gland. (*By courtesy of Sir John Fraser.*)

the latter condition can be clinically distinguished from an ordinary pyogenic cervical abscess by noting that: (1) although the skin is red and thinned it is not œdematous; (2) fluctuation can be obtained across the whole area of reddened skin, and not only in its central part; and (3) the fluid collection is always lax and never tense (fig. 2237).

In *differential diagnosis*, tuberculous glands in the neck may sometimes be mistaken for the following conditions: (1) Simple (pyogenic) adenitis; (2) Hodgkin's disease; (3) malignant disease, e.g. lymphosarcoma or secondary carcinoma; (4) glandular fever; (5) lymphatic leukæmia; (6) carotid body tumour; (7) branchial cyst; (8) sebaceous cyst; (9) aberrant adenoma of the thyroid or thyroglossal cyst; (10) fibroma, lipoma, etc.; (11) dermoid cyst; (12) ranula; (13) actinomycosis; (14) cellulitis; (15) syphilitic disease of the

glands or gumma of the sterno-mastoid muscle; and (16) tumour of the submaxillary or parotid salivary glands.

Pathology. The pathological appearances of tuberculous glands in the various stages of the disease have already been discussed on page 4121, but it is necessary here to describe from the clinical aspect the three distinctive pathological types of tuberculous cervical adenitis:

(1) The caseous type; (2) the lymphoid type; and (3) the fibrous type.

The *caseous* type is most frequently seen in children, and here the glands, which at first are discrete, become matted together and soften, eventually leading to the formation of a cold abscess. A cold cervical abscess, which is sometimes termed a "collar-stud" abscess, occurs when the pus bursts through the capsule of the gland, burrows through the deep fascia, and forms a collection in the subcutaneous tissues. The communicating channel through the deep fascia is usually very narrow, and when such an abscess bursts through the skin or is incised, a chronic sinus is produced. In the *lymphoid* type the nodes are discrete and elastic, there being usually no peri-adenitis. If, however, this occurs, it is a late phenomenon, as is also caseation. This type is particularly difficult to diagnose from Hodgkin's disease, and even on microscopical section such differentiation may in certain cases be impossible. In the *fibrous* type, which is seen chiefly in adults, the glands are small, hard, shotty, and firmly adherent to the deep structures. The disease pursues a very chronic course.

Clinical Features. There are two main clinical types of the disease:

Type I—the Diffuse Type. Here adenitis is a manifestation of widespread tuberculosis, and the primary infection is situated in the mesenteric or mediastinal glands, and occasionally in the parenchyma of the lung itself. The chief features common to this type may be enumerated as follows: (1) The general health of these patients is usually poor, and they are thin, pale and anæmic; (2) there is generally active and obvious disease present in the tracheo-bronchial lymphatic glands, in the mesenteric glands, or in the lungs; (3) the glands are not greatly enlarged; they are soft in consistency, and often partially calcified; (4) the involved cervical glands are multiple, and are situated in both sides of the neck, and particularly in the posterior triangles, being frequently associated with enlarged nodes in the groins and axillæ; (5) the tonsils are not usually enlarged or septic, and adenoids or any associated affections of the throat are seldom present; the enlargement of the glands is, as a rule, first noticed after the age of puberty; and (6) the prognosis must always be guarded.

Type II—the Localised Type, which is far more common than *Type I*, and is seen chiefly in adolescence. Here the infection is purely a local one, originating in the tonsils, adenoids, or, more rarely, in the teeth, etc. There are four chief clinical features of this type: (1) The general health is good, there being no evidence of tuberculous lesions elsewhere; (2) one particular gland, usually the jugulo-digastric or tonsillar, is, as a rule, chiefly involved, other surrounding glands being affected to a lesser degree; calcification is rare; (3) the tonsils and adenoids are often enlarged and septic, there being frequently a history of repeated attacks of tonsillitis or dental trouble; and (4) the prognosis after removal of septic foci followed by appropriate treatment of the glands is good.

The *course of the disease* may be divided into three distinct stages: (1) The stage of latency; (2) the stage of hyperplasia and the early formation of tubercles; and (3) the stage of caseation, sometimes accompanied by the formation of abscesses and fistulæ. In the early stage of latency, the general condition is good. The glands themselves are moderately enlarged, indolent and painless, there being no other symptoms of any consequence. At a later stage, when caseation occurs, there will be malaise accompanied by languor, and there may or may not be a slight evening rise of temperature. When frank suppuration ensues, there will be a stiffness of the head and marked pain and tenderness over the indurated mass of glands in the neck. Should an abscess form it may become secondarily infected, and the overlying skin may become red and œdematous. When, however, the abscess bursts through the skin, pain and tenderness are at once relieved. At a late stage in the disease in neglected cases, when there is multiple involvement of the glands and abscess formation, the general condition will be poor, with asthenia, anorexia and fever, together with the danger of dissemination of the disease—miliary tuberculosis or tuberculous meningitis.

The following are some *common clinical types* of tuberculous adenitis belonging to Type II, each of which calls for a special line of treatment which will be described later: (1) A simple enlarged firm gland or group of glands; (2) diffuse indurated swelling, i.e. inflamed glands matted together owing to peri-adenitis; (3) fluctuating glands; (4) a cold abscess—collar-stud abscess; (5) chronic discharging sinus in the neck due to an abscess which has burst; and (6) tuberculosis of the skin in the region of the orifice of a sinus in the neck, or as the result of involvement of the skin from the wall of a tuberculous abscess.

Prognosis. The prognosis depends upon several factors, such as: (1) The type, virulence, and site of the infection; (2) the resistance of the patient; and (3) a correct choice of treatment for each individual case.

In a general way it may be stated that in the majority of cases of tuberculous adenitis the patient's life is not directly threatened, but the infection is of a very chronic nature and treatment may be necessary for a considerable period, extending over months, and in many cases even years. It is, in fact, one of the least dangerous of the many forms of tuberculosis, as the disease is usually localised to the neck and rarely becomes disseminated. Disability is not marked, and in most instances the patient seeks treatment at an early stage on account of the unsightly lump in the neck and through fear that if an abscess forms it may burst through the skin. It is important to establish as far as possible whether the disease in the neck is blood-borne or lymphatic-borne. If the latter is the case, the prognosis is good, as the enlarged glands are evidence of a local infection and local resistance; whereas in a blood-borne infection there is always the danger of tuberculous septicæmia and spread of the disease to other organs.

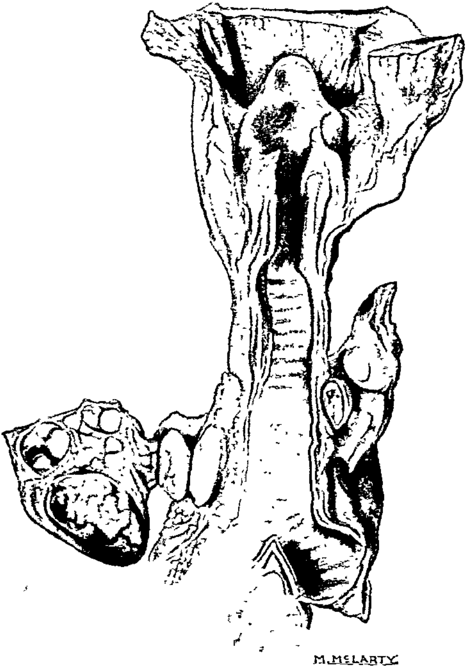
As already stated, the prognosis is definitely bad during the first two years of life, as the disease is then eager in its course, and death from tuberculous meningitis often ensues. The prognosis is good when the tonsillar gland or the glands in the upper deep cervical group are involved. It is, however, more serious when the supra-clavicular nodes are infected, when both triangles of the neck are simultaneously involved, or when the disease shows a haphazard distribution, e.g. a few scattered swollen glands in the neck, and obviously enlarged glands in the axillæ.

The *treatment* of tuberculous glands in the neck is discussed on page 4145.

(B) *Tuberculous Disease of the Mediastinal or Tracheo-Bronchial Glands*

Tuberculosis of the tracheo-bronchial glands is primarily a disease of childhood, and the treatment is wholly medical. In children the infection is usually by the bovine strain, whereas in adults it is chiefly of the human type. The point of entrance of the infection is nearly always in the intestinal tract or in the bronchial tree. The tubercle bacilli penetrate the mucous membrane of the small intestine or bronchioles, and are carried to the nearest lymphatic gland. Here they may become imprisoned, or they may escape and travel by way of the veins to the right heart, and thence to the lungs. In children the bacilli, which

are brought here by the blood stream, may form a small, relatively innocent focus in the lung (Ghon's focus) which heals spontaneously without clinical symptoms, or may pass directly through the lungs without being arrested until they are finally entrapped by the tracheo-bronchial



...NDS. (*Museum, London Hospital*)

glands where they light up a chronic infective process (fig. 2238). This gives rise to a vague combination of symptoms which may be grouped as follows: (1) Sallow complexion; (2) undue fatigue; (3) irritability and peevishness; (4) anorexia and malnutrition; (5) intermittent pyrexia; and (6) paroxysmal coughing.

It is *almost impossible to make a correct diagnosis* by ordinary physical methods and by radiological examinations before calcification has taken place in the diseased glands, but the condition may often be rightly suspected if, in the absence of physical signs in the chest and

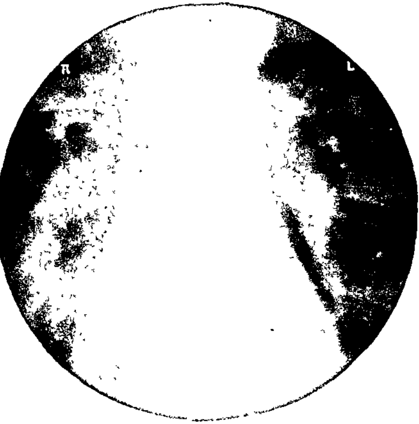


Fig. 2239.—Calcification of the tracheo-bronchial glands. (*Bull.*)

with negative X-ray findings, it is known that the patient has been exposed to the infection, if it is seen that he is rapidly losing ground, and if the tuberculin test is strongly positive. When skiagrams show calcification of the tracheo-bronchial glands it implies that the disease is well established or healed, having been present for a period of at least some months (fig. 2239).

If suppuration occurs in the mediastinal glands, an abscess may form and press upon the following structures:

(1) The *trachea*, causing shallow breathing and weak respiratory murmurs all over the lungs. (Dyspnœa may be alarming and may be accompanied by

explosive and paroxysmal attacks of coughing.) (2) The *bronchus*, causing absent or diminished respiratory sounds and restricted mobility of the affected side. (3) The *œsophagus*, causing dysphagia. (4) The *recurrent laryngeal nerve*, causing loss of voice or hoarseness, often accompanied by paroxysmal coughing. (5) The *superior vena cava*, causing obstruction of the large veins of the neck and face, arms and shoulders. (6) The *vagus nerve*, causing tachycardia and even vomiting. (7) The *sympathetic nerve trunk*, causing dilatation or contraction of the pupil on the affected side from pressure or irritation. (8) The *thoracic duct*, causing rupture and chylothorax.

The abscess may rupture into the following sites:

(1) The *trachea*, causing violent coughing, dyspnœa, or even death from suffocation. (2) The *pleura*, producing pleural effusion or empyema. (3) The *pericardium*, causing an embarrassment in the heart's action. (4) The *large blood-vessels of the mediastinum*, causing a widespread dissemination of the disease. (5) The *œsophagus*, causing dysphagia and the vomiting of tuberculous pus. (6) The *posterior mediastinum*, tracking round to the surface of the skin where it may form a localised abscess and eventually discharge through the skin, the axillæ and supra-sternal notch being common sites.

Treatment. This consists of: (1) Isolation of the patient and institutional treatment; and (2) general prophylactic measures, such as prolonged rest, and abundance of fresh air, sunshine, nourishing food with an ample vitamin content and the inclusion of malt and cod-liver oil, and, possibly, X-ray or tuberculin treatment.

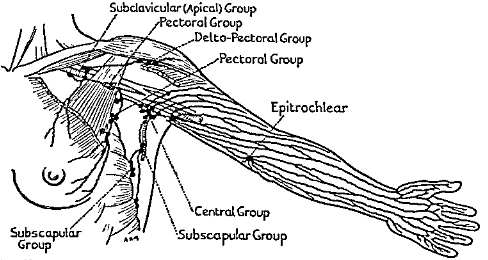

Fig. 2240.—A SCHEME OF THE LYMPHATIC GLANDS AND LYMPHATIC VESSELS OF THE UPPER EXTREMITY AND AXILLARY REGION.

(C) *Tuberculosis of the Axillary Lymph Glands* (fig. 2240)

The axillary lymphatic glands may become infected with tuberculous disease in three chief ways:

(1) From a local tuberculous lesion, e.g. tuberculosis of the breast,

anatomical tubercle of the hand, such as may occur following the performance of a post-mortem examination, etc. (2) By extension from tuberculous glands in the neck, and especially the lower deep cervical group of glands. It is nevertheless possible (though very rare) that organisms may gain entrance through the throat, and pass by a direct route through the lymphatic systems of the neck without involving them, and thence to the axilla, producing tuberculous

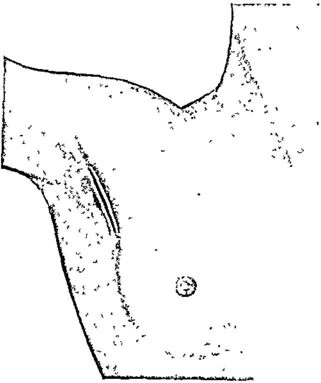

Fig 2241.—The incision employed for exposing a mass of tuberculous glands in the axilla or lying deep to the pectoralis major muscle.

lymphadenitis in the nodes in this region: (3) As a part of a generalised infection of the lymphatic system.

Treatment. Where tuberculosis of the axillary glands is a part of a generalised tuberculous process, the treatment should be conservative and follow general lines. Where, however, the disease is definitely localised to one or more of the axillary glands, the best treatment is prompt excision of all palpable infected nodes. No object will be gained by delay, as abscess and sinus formation so frequently occur, making subsequent dissection most difficult.

The best approach to these axillary glands is obtained by an incision which is made parallel to and a little behind the upper half of the anterior fold of the axilla (fig. 2241). The dissection is carried downwards through the deep fascia, the pectoralis major muscle is retracted upwards and inwards, and the glands are freed from the

great vessels and nerves of the axilla. When multiple sinuses are present it may be advisable to curette them and follow up the treatment by applications of X-rays. If this fails, then the mass should, where possible, be completely dissected out.

(D) *Tuberculosis of the Inguinal Glands* (fig. 2242)

This is a rare condition, even less common than tuberculosis of the axillary glands. It nearly always results from a local area of disease,

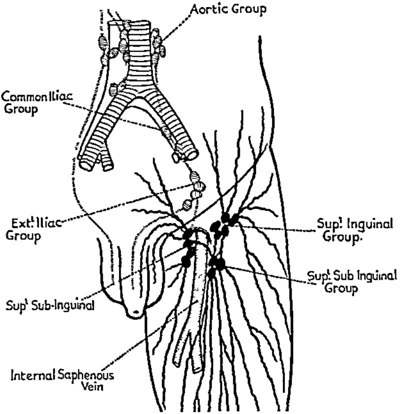

Fig 2242.—Scheme of the inguinal lymphatic glands.

such as tuberculous ulcer of the vulva or peri-anal region, or tuberculosis of one of the joints of the lower extremity. Occasionally, however, the infection may be blood-borne, when other glands also are usually involved.

On examination of such cases it is important to exclude venereal disease, and a meticulous search of the whole area must be made for any evidence of a local tuberculous lesion, an infected wound, or the scar of a recent wound. The glands themselves are enlarged, somewhat matted together, and tender on pressure, while there may be some associated stiffness of the limb. As it is important to make a prompt

diagnosis in these cases, it is often necessary to remove a gland and submit it to microscopical scrutiny so that suitable treatment may be instituted without delay. Tuberculous disease of the inguinal glands must be distinguished from the following conditions: (1) Acute pyogenic lymphadenitis; (2) inguinal and femoral herniæ; (3) bubo secondary to syphilis or soft sore; (4) lymphogranuloma inguinale;

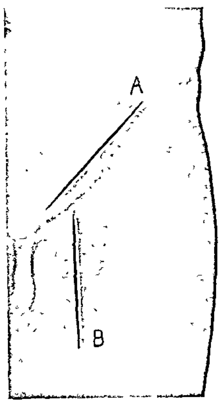

Fig. 2243.—A. Incision employed for dissection of external iliac group of glands. B. Incision for dissection of inguinal group of glands

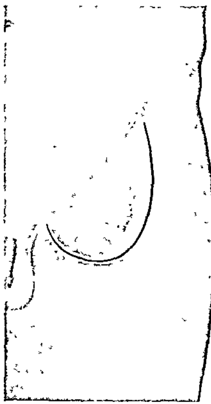

Fig. 2244.—Curved incision sometimes employed for exposure of inguinal glands.

(5) psoas abscess; (6) Hodgkin's disease; (7) primary or secondary malignant glands of the groin; and (8) encysted hydrocele of a hernial sac.

Treatment. Small lymphatic glands which are causing little or no inconvenience and which are not rapidly becoming larger may be treated by conservative measures. Those, however, which are large—and particularly those in which considerable matting has occurred and formed a definite tumour—are best treated by excision, when a portion of the saphenous vein may have to be removed together with the infected glands. The incisions commonly employed for dissecting out infected glands in the groin are depicted in figures 2243 and 2244.

When the *external iliac glands* which lie to the outer side of the

external iliac vessels are involved, they may be removed by making a transverse incision through the skin and abdominal muscles, $1\frac{1}{2}$ inches above the outer half of the inguinal ligament. After retracting the upper edge of the incision firmly upwards, the peritoneum is exposed and stripped off the glands, which are thus brought into view so that they can be dissected out.

(E) *Tuberculous Mesenteric Lymphadenitis*

The lymphatic glands of the abdomen are classified into two large groups, visceral and parietal, each of which is sub-divided into smaller groups according to the organs or regions they drain.

Thus:

Visceral	Parietal
gastric.	iliac.
pyloric.	lumbar.
splenic.	sacral.
hepatic.	aortic.
pancreatic.	anterior abdominal.
mesenteric.	
ileo-cæcal.	
colic.	
cœliac.	

In tuberculous mesenteric lymphadenitis the lymph glands of the mesentery and retroperitoneal space become enlarged, and often caseate: occasionally they suppurate or calcify, calcification being more frequent (fig. 2245). The condition is most often seen in early childhood, when it must be assumed that it originates from the consumption of milk obtained from tuberculous cattle. The incidence varies very considerably in different parts of the world, as John Thomson has emphasised. He writes:

> "Scotland enjoys the unenviable distinction of having more abdominal tuberculosis than any other civilised country—twice as much as England generally, and more than ten times as much as Europe and North America."

The disease may be a primary lesion, or may be secondary to tuberculosis of the intestine or lungs. In the *primary* cases, the glands become infected without there being any evidence of disease in the intestine. It must therefore be inferred that the bacilli have passed directly through the intact intestinal wall, or that a small lesion has formed which has healed so completely that no evidence of it remains. In the *secondary* cases, there are gross tuberculous lesions in the lungs or intestines which account for the lesions in the abdominal glands. The commonest sites of infected lymph nodes are the ileo-cæcal angle,

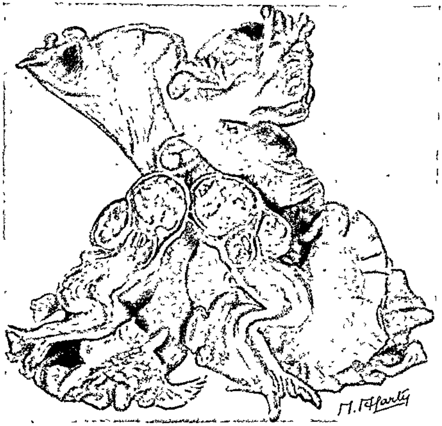

Fig 2245.—Tuberculous glands in the mesentery. (*Museum, London Hospital.*)

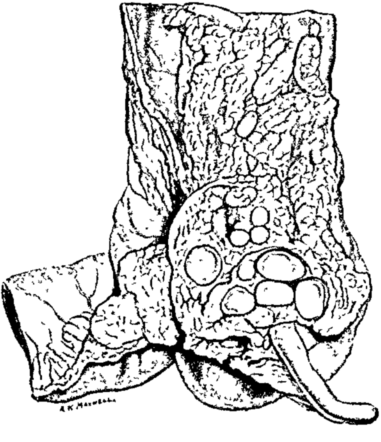

Fig. 2246.—Tuberculous glands of the ileo-cæcal region (posterior aspect). (*Museum, Royal Infirmary, Glasgow.*)

the retroperitoneal spaces medial to the cæcum and ascending colon, and the lower part of the mesentery of the small intestine. Occasionally a single chain of glands will be seen following the course of the ileo-colic artery to the root of the mesentery (see fig. 2246).

Diagnosis. On X-ray examination, visceral mesenteric glands, when calcified, have a conglomerate appearance like the aggregation of many small particles, the ileo-cæcal group being the one most commonly affected (fig. 2247). These calcified glands are found in the right iliac fossa; they can be palpated in thin patients, and are sometimes

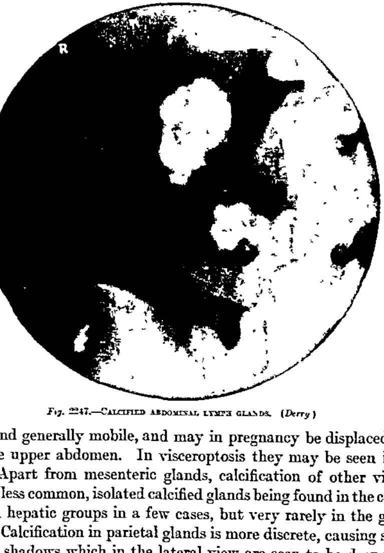

Fig. 2247.—Calcified abdominal lymph glands. (*Derry*)

tender, and generally mobile, and may in pregnancy be displaced high up in the upper abdomen. In visceroptosis they may be seen in the pelvis. Apart from mesenteric glands, calcification of other visceral groups is less common, isolated calcified glands being found in the cœliac, colic and hepatic groups in a few cases, but very rarely in the gastric groups. Calcification in parietal glands is more discrete, causing single, clear-cut shadows which in the lateral view are seen to be deep in the abdomen. Such shadows may be difficult to differentiate from renal calculi. Of the parietal glands the anterior abdominal group is very rarely calcified. The most difficult differential diagnosis is between a

calcified lumbar gland adjacent to a kidney pelvis and a renal calculus. These two conditions cannot be differentiated by antero-posterior and lateral films as in the other groups, and it is necessary both to examine the renal pelvis with a pyelogram and to take the clinical evidence into account. In the same way, gall-stones are distinguished by a cholecystogram. Calcified fibroids and lithopædion are larger than glands. Calcification around a foreign body assumes the shape of that body. The teeth in dermoids are usually recognisable as such. (Horny warts on the skin may throw shadows like those of calcified glands.)

Golden and Reeves found that in 23 of 29 unselected cases the glands were situated in the right lower quadrant of the abdomen. This localisation is attributed by them to the normal slowing up of the intestinal contents in the ileum, cæcum and ascending colon, which gives the organisms a better opportunity of passing through the walls here than elsewhere in the intestinal tract. All stages of the tuberculous process may be found in these mesenteric lymphatic glands—tubercle formation, caseation, and calcification. The older the patient, the more likely the glands are to contain calcium ; in young patients it is the exception, although occasionally a large, thick-walled, cystic tumour may be found which resembles a dermoid and contains yellow creamy material, together with depositions of chalk.

The disease is very protean in its clinical manifestations, but frequently three varieties may be recognised:

Clinical Types. In the *acute* type, which is so commonly seen in children, the symptoms mimic those of acute appendicitis, acute gastroenteritis, acute pyogenic abdominal lymphadenitis, or "gastric influenza." The patient feels languid and ill, and complains of intermittent bouts of abdominal pain specially referred to the umbilicus or right iliac fossa. The pain may be dull and dragging in nature, or sharp and colicky. Sometimes there are severe attacks accompanied by nausea and vomiting, and the pain may radiate to the back or down the thighs. After a day or two the pains tend to subside, only to recur later with added acuteness. The patient suffers from lack of energy of mind and body ; fever is usually continuous (99°–105° F.), although it may sometimes be intermittent ; and there may be constipation, although diarrhœa is the rule, the stools being thin, watery, dark, and extremely offensive. Diarrhœa is more likely to be present if there is any associated ulceration of the intestine. The face is pale, with flushed spots on each cheek, the lips are dry, the tongue coated, the breath foul, the extremities wasted, and the abdomen distended, tumid, and tender on palpation. This tenderness is most noticeable in the right

iliac fossa or in the hypogastrium, and on deep palpation one or two painful areas or palpable masses may be made out.

These cases are usually submitted to operation after a variable period of watchfulness and the performance of serological tests, a diagnosis of ? retrocæcal or pelvic appendicitis usually being made. At operation the appendix will be sought for, and although it will often be found to be normal in appearance it should, nevertheless, be removed in all cases. A little clear free peritoneal fluid will be present, and this must be quickly mopped up or evacuated by means of a suction tube. The glands in the mesentery and retroperitoneum are extremely plentiful, slightly enlarged, and rubbery in consistency; there is little or no peri-adenitis, but one or two nodes here and there may feel hard and gritty. *After removing a gland for biopsy, the abdomen should be closed without drainage.* The post-operative results are on the whole eminently satisfactory, although it is difficult to understand why this should be so. In some cases convalescence will be stormy, and recovery to health slow, while in a few cases death will follow from a rapid spread of the tuberculous process or from generalised tuberculosis.

In the *chronic* type of the disease, the involvement of the glands gravely interferes with nutrition, and the patient is wasted and anæmic, and tires easily on exertion. The symptoms are intensified by the frequent association of local tuberculous peritonitis. The abdomen is distended and tympanitic, but owing to the distension no enlarged glands can, as a rule, be felt. In some cases, however, nodules or a freely movable tumour mass can be made out to the right of the umbilicus. Diarrhœa is a constant feature, and the fat-laden stools are bulky, whitish, frothy from fermentation, and malodorous. There is a moderate pyrexia, but the general wasting and weakness are the most characteristic features. Anorexia, gastric upset, chronic abdominal pain, the discomforts associated with a gradually increasing distension of the abdomen, lassitude and drowsiness are the usual symptoms of which the sufferer from this disease complains.

The treatment of this condition is primarily medical, but during the course of the disease the following complications may occur and call for surgical measures: (1) Intestinal obstruction, which may be acute or chronic and which is due to adhesions which form between the breaking-down nodes and a neighbouring portion of the gut; (2) pressure effects upon neighbouring structures, e.g. at the root of the mesentery, compressing the third part of the duodenum and so producing duodenal ileus, or pressure or dragging upon the ureter causing ureteric colic or hæmaturia; and (3) perforation of a breaking-

down lymphatic gland, simulating ruptured appendix and causing a localised abscess or diffuse peritonitis.

In the *third* type, the disease is spent, and only the chalky tombstones of the dead bacilli remain as witnesses of the struggle that has once taken place. But although calcified abdominal glands are often clinically silent and innocuous, they may at times be the cause of recurrent crippling abdominal pains, severe colic, intermittent hæmaturia, or even intestinal obstruction.

Calcified abdominal glands are encountered in 65 per cent of subjects in the course of routine X-ray examinations. They are not commonly met with before the age of 12, and the sexes are affected with equal frequency. It is interesting to reflect that in the great majority of patients who have them, the glands affected are those of the ileo-cæcal group. This is a small group—four or five glands at the most—and yet it is the group picked out for tuberculous infection in about half the population.

Thomson-Walker found that in 11 out of 42 cases the symptoms were sufficiently severe to justify the removal of the calcified glands by operation. The result in all these cases was the disappearance of the pain, whether it had been in the nature of recurrent attacks of colic or of continuous dull aching. It is generally agreed that, since these glands represent the terminal stage of the disease and since, given careful surgical technique, there no longer exists a danger of dissemination of the tubercle bacilli, the question of whether to operate or not should depend upon the severity of the symptoms. Operation is only justifiable when the pain is recurrent and severe and is considered to be directly due to the presence of the glands. In those cases where hæmaturia is due to dragging on the ureter by a mass of glands, the abdomen should be opened and the culpable glands removed.

CHAPTER III

The Treatment of Tuberculous Glands in the Neck

by

Rodney Maingot

Treatment may be either conservative or surgical. Conservative measures include all those which aim at a natural cure short of any attempt to excise a solitary gland or a group of glands. Although there are many adjuvants to conservative treatment, with regard to the value of which there are still differences of opinion, the main issues at stake in the treatment of this disease are the correct moment at which operation, if any, should be advised and the form it should take.

In a large number of cases a natural cure can be effected by adequate conservative measures before massive caseation has occurred in the glands. After this has taken place, there are only two methods of cure apart from operation: (1) The gradual replacement of the cheesy material in the gland by chalk; and (2) the complete caseation of all the glandular tissue, its subsequent softening and discharge through a sinus in the neck, and, finally, the shrinking and fibrosis of this sinus and the remaining gland capsule. Nature's method of cure, therefore, after extensive caseation has occurred, leaves unsightly masses or ugly puckered and depressed scars in the neck. Nature may be an excellent physician, but she is a crude surgeon. It would thus appear obvious that, in order to effect a rapid eradication of the disease with a minimum amount of scarring, surgery is clearly indicated after this stage has been reached.

GENERAL CONSIDERATIONS

It is impossible to lay down any definite rules to cover the treatment of all patients suffering from this disease, as so many factors influence the decision in each individual case. The following general considerations should, however, be borne in mind:

(1) The *age* of the patient may affect the choice of treatment. For instance, in infants up to 2 years of age conservative treatment should be persevered with, and if an abscess forms it should be treated on the simplest lines by incision and drainage. Older children, on the other

hand, are ideal subjects for radical operation. In adults exhibiting the characteristics of Type II of the disease (see page 4130), when softening of the gland takes place, operation should be undertaken without hesitation, for, although a noticeable scar may result, the disease, which would otherwise run a protracted course, is thus promptly eradicated. In old people the condition is comparatively rare and benign, and conservative measures should be persevered with unless the glands are *producing much pain or persistent discomfort.*

(2) The *occupation and the economic status* of the patient are often factors to be considered in the choice of treatment. For the average

Fig. 2248.—Tuberculous glands in the neck. (*By courtesy of Sir John Fraser.*)

patient who cannot afford the time or the expense of a prolonged course of conservative treatment, operation should be advised.

(3) The *extent and type of the diseased glands*, in other words, the pathological stage reached, will often be a determining factor in deciding upon the therapeutic measures to be adopted. For instance, a young adult who has no signs of active tuberculosis elsewhere in the body, and in whom the tonsils and adenoids and other local foci of sepsis have been removed, may present a number of different clinical manifestations calling for various lines of treatment. Ten examples of these are given below :

(*a*) A single mass of glands in the carotid triangle on one side of the neck, if seen early, requires conservative treatment ; but if, on the other hand, the disease is well developed and there are areas of softening, excision of the infected nodes should be undertaken (fig. 2248).

(*b*) *A mass of glands in each carotid triangle should be dissected out if there is no improvement after a brief course of medical treatment.*

(*c*) A mass in the submaxillary region on one or both sides indicates excision.

(*d*) A mass in the supra-clavicular region may, if small, be submitted to expectant treatment; but if it is large and gradually increasing in size, excision is to be preferred.

(*e*) Small scattered lymph nodes in one posterior triangle call for conservative measures, combined with X-ray or light treatment.

(*f*) Many scattered, small, discrete glands in one or both sides of the neck are an indication for general measures.

(*g*) A large mass may be found in one side of the neck with marked periadenitis. *Here local palliative measures are at first indicated. The head and neck* should be splinted, and fomentations applied.

(*h*) A "collar-stud" abscess should be opened, the aperture in the deep fascia

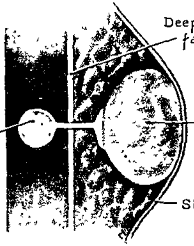

Fig. 2249.—Collar stud abscess

located and dilated, and the offending gland curetted out or completely excised (fig. 2249).

(*i*) *A large subcutaneous abscess, with the overlying skin thin and red, should* in the first instance be incised and its walls lightly curetted.

(*j*) *A sinus or sinuses in the neck without any appreciable underlying mass may* yield to heliotherapy and perhaps to X-ray treatment. If, however, there are persistent palpable underlying nodes, the sinus and the associated *glands should* be removed.

(4) The *presence or absence of tuberculosis elsewhere in the body* greatly influences the choice of treatment. *If the enlarged nodes in* the neck are a manifestation of a general disease, it is obvious that conservative measures should be persevered with indefinitely.

Conservative Treatment.

Under this heading the following points call for special consideration: (1) The elimination of all possible sources of local infection; (2) rest and attention to the general health, necessitating in certain cases

sanatorium treatment; (3) local adjuvants, which include: (*a*) applications to the affected glands; (*b*) aspiration of a tuberculous abscess, or aspiration followed by the injection of some antiseptic or sclerosing solution; (*c*) heliotherapy; (*d*) tuberculin treatment; (*e*) radio-therapy (radium or X-rays); and (*f*) drugs.

The object of conservative treatment is to increase the natural resistance of the body by general and local measures, so that the course of the disease is arrested. As John Fraser puts it:

> "The various measures adopted under this scheme so increase the local vascularity and resistance that barriers of fibrous tissue are deposited around the diseased focus, the effect being to isolate the disease, to cut off its nutritional blood supply, possibly to strangle it by mechanical constriction, and eventually to convert it into a knot of fibrous or calcified tissue."

The *eradication of local septic foci* is the first step in treatment, and the tonsils, when present, should be enucleated by dissection *in every case* without question, whether they appear to be diseased or not. If there is adenoid tissue this also should be removed.

The measures usually adopted to improve the *general health* comprise fresh air and sunshine, a well-balanced diet, adequate sleep, rest (general and local), the best hygienic conditions possible, and careful attention to the bowels. Rest in bed with immobilisation of the head and neck will often have a surprising effect in producing both a subsidence of the glands and an all-round general improvement in the patient's condition. Ambulatory cases should be fitted with a poroplastic collar which holds the head rigid and does not exert any harmful pressure upon the glands. The collar is well padded with wool, and is worn both by day and by night.

Amongst the local adjuvants, *fomentations* will be required where there is marked peri-adenitis, or when a secondary infection is superimposed upon a cold abscess for which drainage has been provided. *Counter-irritants*, such as painting the neck with iodine or the use of iodine ointments, have been recommended for early mild cases before caseation has occurred; but such measures are generally deemed to be meddlesome and injurious. *Simple aspiration* of a tuberculous abcess in the neck may be indicated as an emergency measure, particularly when arrangements for operation cannot be made expeditiously. It is, however, an unsatisfactory routine method of dealing with the condition, as more often than not the fluid proves difficult to withdraw owing to its high degree of viscosity and owing to the needle so frequently becoming clogged with thick tuberculous debris. Again, the cavity soon refills, thus necessitating frequent repetition of the pro-

cedure, which is not free from a danger of the introduction of secondary infection, even though care be taken to thrust the needle through healthy tissue and not through the most prominent part of the swelling where the skin is thin and devitalised. The injection of antiseptic and sclerosing solutions into the abscess-cavity provokes sinus formation rather than a process of healing.

All observers are agreed that *heliotherapy*, real or artificial, is an important feature in the treatment, and it requires no further emphasis, as its benefits are so well known and outstanding. *Tuberculin* has at times been extensively used in this country in the treatment of tuberculous lymphadenitis, but it is as yet almost impossible to assess its true value. It is generally thought, however, that even Beraneck's tuberculin is not likely to arrest the tuberculous process once extensive liquefaction has occurred. Nevertheless, the results when treatment is instituted in the stage of peri-adenitis without softening are considered by Thompson to be very promising.

Radium and *X-rays* are both useful local remedies, but the dosage must be very carefully measured and the treatment be administered only by a skilled radio-therapist. Tuberculous glands in the stage before breaking down has occurred respond very well to radio-therapy in a large proportion of cases. The treatment is given in small weekly doses over a period of two to three months. It should here be stressed that excessive dosage may lead to rapid breaking down, and thus the most propitious moment for surgery may be missed. Glands which have broken down and which are discharging can sometimes be made to heal in a most satisfactory manner by means of X-rays, but here much depends upon the extent of the suppurative process. *Large* masses of broken-down glands with multiple sinus formation do not offer much hope of relief by this method of treatment, although occasionally striking results are obtained. On the other hand, *small* gland masses with one or two discharging sinuses may respond with remarkable rapidity and heal completely within a few weeks. It is generally accepted that although X-ray treatment has a definite place in the management of cases of tuberculous glands in the neck, it is not, as a rule, to be recommended where there is abscess formation, where calcification or caseation is evident, or where the enlarged glands in the neck are complicated by secondary infection. The mode of action of X-rays in tuberculosis is not clear, as it has been incontrovertibly proved that no effect upon the tubercle bacilli is obtained with clinical dosage.

Treatment with *ultra-violet rays*, both by local and general

applications, has been recommended by some authorities for the following types of cases: (i) Superficial sinus or scrofuloderma; (ii) scattered enlarged nodes in one or both triangles of the neck; and (iii) in certain instances following radical excision, particularly where an extensive dissection has been effected. But, in my opinion, the majority of cases submitted to ultra-violet rays become worse while undergoing treatment, a fact which is also confirmed by Thompson (*St. Bartholomew's Hosp. Reports*, LXIX, 1936, 215). The *drugs* which are now most commonly prescribed are halibut- or cod-liver oil, and iodides, and these are usually given as a routine. Iodides are best administered in the form of syrup ferri iod. (B.P.) in full doses for periods ranging from two to three years, and are particularly useful in those cases where the glands have not reached the stage of gross caseation.

Operative Treatment.

According to the pathological state reached by the gland or group of glands affected, operative treatment will consist of: (1) Dissection of the involved gland or group of glands; (2) incision, evacuation, and curettage; or (3) secondary removal of a residual gland following (2). A detailed description of each of these methods will be given later.

Although excision of tuberculous glands in the neck was formerly a very common procedure, nowadays operation is only advised after careful deliberation and with discrimination. The nature of the operation will therefore depend upon the position and extent of the disease, whether or not an abscess or a sinus is present, and whether one group of glands or more is involved. Operation is indicated under the following conditions: (1) Where a group of large glands in the neck shows no signs of resolution after removal of all septic foci and after a course of conservative treatment; (2) when, in the local type of the disease, the glands are spreading from one group to another; (3) if there is any evidence of softening; (4) in all cases of abscess formation; (5) where, after incision and drainage of a cold abscess, a residual mass remains which shows no evidence of subsiding under palliative measures; (6) where one or more long-standing, mobile calcified masses cause unsightly tumours in the neck; and (7) in certain cases for cosmetic or economic reasons.

There are five main *contra-indications* to operation: (1) If the infection in the glands is believed to be blood-borne; for instance, where there is a haphazard distribution of the glands in the neck, associated with enlarged nodes in the axillæ or groins; (2) in children under two years of age; (3) in the senile and fibrous types of the disease; (4) in the stage of acute peri-adenitis; and (5) some cases where the

disease is seen at an early stage, when the gland, or group of glands, is small and mobile and there is no evidence of caseation. Here conservative measures are generally considered likely to prove successful.

It is in the last mentioned type of case that there is such sharp difference of opinion as to the relative merits of radical measures and conservative treatment. The opponents of surgical measures maintain that ugly keloid or puckered scars too frequently follow excision ; that nerve paralyses are by no means infrequent ; that it is often difficult to be quite sure that all the diseased glands have been excised ; and that tuberculous glands in the neck are more often than not a general rather than a local manifestation. They also affirm that the results of conservative treatment by modern methods are eminently satisfactory. Those who favour excision are of the opinion that the scar will be almost invisible if the operation is performed by a skilful and careful surgeon who understands the principles of plastic surgery ; that the scars themselves are less to be dreaded than the disease ; that nerve paralyses should not occur if the operation is carried out by one who is familiar with the anatomy of the neck ; that although there is a possibility of recurrence of the disease this is not sufficient to contra-indicate operation ; that in the majority of cases where a complete dissection of all the involved nodes is undertaken rather than a partial operation there should be no recurrence ; and that in most cases tuberculous glands in the neck are evidence of a local disease originating from the tonsils or adenoids rather than of a blood-borne infection.

Such authorities as Dowd, Miller, Tanner, Barrington-Ward, Grey Turner, Clute and Fraser consider that a radical removal of the disease in its early stage can effect a quick and permanent cure with good cosmetic results in over 90 per cent of cases, especially in children over the age of five years, and that the more advanced the disease the more difficult it is to cure by any means.

OPERATIONS FOR TUBERCULOUS GLANDS IN THE NECK

The technique of the various operations will be described under the following headings :

(1) Incision and drainage.
(2) Incision, evacuation, and curettage.
(3) Intra-capsular enucleation of the affected gland or glands.
(4) Radical excision :
 (*a*) General considerations.
 (*b*) Excision of individual groups of cervical lymph nodes.

Intra-Capsular Enucleation

Another operative procedure, deemed by some to be safer than radical excision of the infected nodes, is the "coring out" of the infected lymphoid tissue from its glandular capsule. By this method an incision is made over the glandular mass, and with a minimum amount of disturbance of the surrounding tissues *each* enlarged gland is palpated and a small incision made over it, after which its substance is enucleated, leaving the capsule itself and the surrounding lymphatic vessels intact. Thus the bulk of the infected tissue is removed without opening up any new fields to the spread of the disease.

This operation is superior to an incomplete dissection which cuts across actively diseased tissues and which is liable to cause a diffuse tuberculous cellulitis of the planes of the neck or even a generalised miliary infection.

Radical Excision

General Considerations.

(1) *Preparation of the Patient.* The patient should be admitted to hospital a day or two prior to operation so that he may receive the necessary pre-operative treatment and so that further investigations may be undertaken if required. The bowels should be opened by means of an aperient the day before the operation, and an enema should be given on the morning of the operation. A light diet rich in carbohydrates is prescribed, together with large quantities of fluids. The hair around the ears and back of the head should be shaved, and this area of skin together with the whole neck cleansed with ether soap, rinsed with sterile water, dried, and then painted with tinct. metaphen (Abbott), tannin-alcohol, or some other suitable disinfecting lotion. The use of iodine is not advised as it is very prone to blister the skin, particularly in children. A sterile dressing is applied and the whole neck is lightly bandaged. In males the head is tightly covered with thin gauze, the edges of which are made to adhere to the skin by means of collodion. In females a closely-fitting rubber cap covers the whole head so as to keep the hair away from the field of operation.

(2) *Choice of Anæsthetic.* Premedication should include large doses of atropin or omnopon with scopolamine, this being given about three-quarters of an hour before the actual commencement of the operation. Anæsthesia is induced with nitrous oxide, followed by oxygen and ether, after which a rubber tube is passed into the trachea through the nose, and anæsthesia maintained by the inhalation endotracheal technique (see Vol. I, page 16).

(3) *Position of the Patient.* The patient is placed in the dorsal position flat on the operating table, with a small sand-bag under the shoulders in order to extend the head, which is turned well over to the sound side so as to expose the affected area. After the primary dressings have been removed, the whole operative field is thoroughly painted with the antiseptic solution previously employed, after which towels are arranged so as to exclude all except the actual site of operation. For all operations upon the neck it is essential to have powerful illumination, in certain cases supplemented by a head-lamp, so that every minute structure can be readily identified.

(4) *Instruments.* The skin incision should be made with a fine Bard Parker knife. As soon as this is completed, the knife which has been used is discarded and a fresh one employed for the remainder of the dissection. This has the object of preventing any infection from

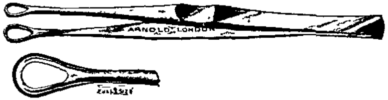

Fig. 2251.—Denis Browne dissecting forceps.

being carried by the knife from the skin surface into the deeper structures. The Mayo pattern of scissors and Dennis Brown dissecting forceps are useful instruments in any case where tuberculous glands require excision (fig. 2251).

(5) *Incisions.* The incisions will vary according to the site and size of the mass or masses to be removed, but all incisions are placed *transversely*, should lie as far as possible in the normal creases of the neck, and should correspond with the lines of stress. Vertical or T- or L-shaped incisions are now never employed for the removal of tuberculous glands in the neck because they leave unsightly scars, and are unnecessary, as there is no mass of glands, however large, that cannot be successfully removed through transverse incisions. Where glands occur simultaneously in the upper and lower parts on one side of the neck, two parallel transverse incisions should be made in preference to one long vertical one. For details of the various incisions employed when dealing with the removal of glands in the different parts of the neck see page 4161. Figure 2252 shows the various methods employed in suturing the wound at the completion of the dissection, A being that chiefly used by the writer.

(6) *Some points in technique.* After the skin incision has been made, tetra-cloths are affixed to the subcutaneous tissues of the edges of the

wound, but not to the skin itself. The incisions themselves should be large enough to afford a clear vision of all the structures. Hæmostasis must be complete and the dissection must be carried out with the utmost gentleness and daintiness, the point of the knife being kept close to the capsule of the gland. There must be no hurry or fluster, and each step must be complete before advancing to the next stage of the operation. Moynihan writes on this point as follows:

"In all the movements of the surgeon there should be neither haste nor waste. It matters less how quickly an operation is done than how accurately it is done.

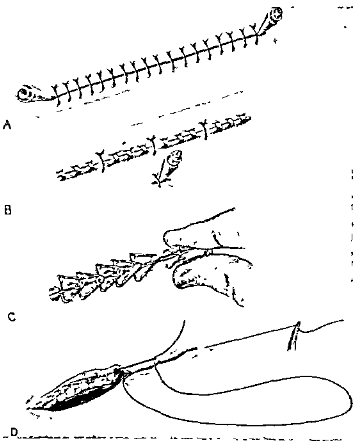

Fig 2252.—Methods of suturing the skin following excision of glands in the neck.
A. Interrupted sutures of fine silkworm gut.
B. Michel clips supported by tension sutures.
C. The insertion of Herff clips.
D Subcuticular stitch.

Speed should result from the method and the practised facility of the operator, and should not be his first and formal intention. It should be an accomplishment—not an aim. And every movement should tell, every action should achieve something. A manipulation, if it requires to be carried out, should not be half-done and *hesitatingly done*. . . . *Infinite gentleness*, scrupulous care, light handling, and purposeful, effective, quiet movements which are no more than a caress, are all necessary if an operation is to be the work of an artist, and *not merely of a hewer* of flesh. For every operation, even those procedures which are now quite commonplace, should be executed not in the spirit of an artisan who has a job to get through, but in the spirit of an artist who has something to interpret or create."

The infected glands must not be grasped with hæmostats or sharp-toothed *forceps for fear of spilling tuberculous material* in the wound. The nodes themselves must not be crudely avulsed with the finger or by blunt dissection with the handle of the knife, and disinfectants should on no account be poured into the wound either during or at the completion of the operation. Blood-vessels which have been clipped should be ligatured at once with fine catgut, and the wound should not be obscured by numerous hæmostats applied to bleeding points. Nothing must be severed *which cannot be identified, and no important structure* must be sacrificed. It is the surgeon's duty to see that such nerves as the spinal accessory and the muscular branches of the third and fourth cervical receive no injury. It is better to leave infected tissue behind than deliberately to injure any important nerve trunk.

The nodes must be removed *en bloc* together with the cellular tissues and fat in which they are embedded. If dissection of the glands is indicated, nothing short of a complete removal of all the involved nodes should satisfy the surgeon if a permanent cure is to be obtained. The tendency nowadays to remove only one or two large glands, leaving the remainder to look after themselves, cannot be too strongly condemned.

Great care should be taken in closing the wound, and the edges of the platysma should be most accurately approximated with closely applied interrupted sutures of fine catgut. Drainage is advisable in all cases, and this is best supplied by means of rubber cigarette drains of fine dental dam. The skin edges are usually united with interrupted sutures of fine silkworm-gut or horse-hair carried on small eyeless needles, the *individual stitches being placed close to one another (almost side* by side) and being tied with the greatest care to avoid tension and cutting or marking of the skin. Occasionally, Michel, Kifa or Herf clips are used, either singly or in combination with interrupted sutures. Most of the clips are removed in 24–48 hours and the stitches on the second, third or fourth day. If, however, a subcuticular stitch is used to approximate the skin edges, it should be left *in situ* for at least a week.

At the completion of the operation the head and neck are bandaged in such a way as to produce immobilisation, but not tightly enough to cause any obstruction of the veins of the neck which will lead to *congestion of the face.*

(7) *Post-Operative Treatment.* When the patient returns to bed, the usual anti-shock treatment is employed. After he has fully recovered from the anæsthetic he is placed in the sitting position, and

the head and neck are further immobilised. The dressings are changed in 24 hours, and the tubes are removed. If metal clips alone have been used to approximate the skin edges, it may be wise to remove the majority on the following day, leaving one or two in position for a further day or two in order to relieve any undue tension on the wound. Any collections of serum should be evacuated, and after each toilet of the wound the neck should be firmly bandaged. After the clips or sutures have been removed, lavish paintings of the wound with double strength calamine lotion are found to be not only agreeable and soothing to the patient but also helpful in reducing any œdema and in hastening healing and the formation of a sound fine scar. Short applications of well-screened radium plaques will reduce any tendency to keloid formation in the scar, and infra-red rays judiciously given have also a beneficial effect in expediting healing of the wound.

(8) *Difficulties, Dangers, and Complications.* The commonest reasons for disappointment following operations for the excision of tuberculous nodes in the neck are the following: an incision which is either too small or not well placed; poor illumination; lack of anatomical knowledge on the part of the operator; attempted excision when peri-adenitis is advanced and adhesions are numerous and firm; septic infection of the wound as a result of bad technique; and dissemination of the infection as a result of diseased tissue being cut across and all the involved nodes not being removed *en masse.*

Some of the more frequent *complications* may be conveniently discussed under the following headings:

(*a*) *Hæmorrhage.* The internal jugular vein may be torn or cut close to its exit from the jugular foramen, causing swamping of the wound with blood. This hæmorrhage can usually be arrested only with the greatest difficulty and with tedious waste of time. Hæmorrhage commonly occurs when the surgeon cuts blindly in the depths of the wound with scissors, or mistakes stretched blood-vessels for strands of connective tissue when undue traction is made upon the nodes during the process of dissection. When these taut blood-vessels are severed they immediately retract out of sight, flooding the wound and rendering the subsequent steps of the operation more difficult by obscuring the structures to be dissected.

(*b*) *Air-embolism.* This is prone to occur when the external jugular vein is cut close to the point where it pierces the deep fascia at the outer border of the sterno-mastoid muscle, just above the clavicle, or whenever the internal jugular vein or one of the other large veins in the root of the neck has been incised or torn across. The condition is

recognised by a sudden gush of dark blood into the wound, accompanied by hissing sounds produced by air being sucked into the vein. This accident may lead to sudden death unless prompt emergency measures are taken to check the entry of air into the circulation by pouring saline into the wound, by digital compression of the aperture in the vein, or by grasping the severed ends with hæmostats. In certain cases where the patient appears moribund after such an accident and shows no signs of recovery, it may be wise to make an epigastric incision, compress the heart, and squeeze it against the chest wall. This method of massaging the heart constitutes a rational attempt to force the bubbles of air onwards into the pulmonary vessels, but its chances of success are very remote, irremediable damage having already been done to the central nervous system.

(c) *Wounds of the thoracic duct.* (See page 4099.)

(d) *Formation of a hæmatoma* or cystic swelling due to exudation of divided lymph vessels. Should a cystic swelling form, the fluid should be evacuated by removing a stitch or two, or by probing the wound with sinus forceps. A small rubber tube or a strip of corrugated rubber should be inserted into the wound and stitched into position.

(e) *Injuries to important nerves.* The nerves most frequently injured in operations for tuberculous glands in the neck are the spinal accessory, the cervical branch of the facial nerve, the muscular branches of the third and fourth cervical, and the hypoglossal. If the spinal accessory nerve is severed before it pierces the sterno-mastoid, the muscle becomes partly paralysed and atrophic, but movements of the head are not greatly impaired, and there is no subsequent torticollis. Division of the nerve in the posterior triangle causes partial paralysis of the trapezius muscle, but no disability of any great consequence. Division of the muscular branches of the third and fourth cervical nerves together with division of the spinal accessory nerve causes paralysis of the trapezius muscle with atrophy. The shoulder on the affected side droops, and the inferior angle of the scapula becomes very prominent and is rotated towards the spine. The cervical branch of the facial nerve is too frequently divided during operation for removal of the upper deep cervical group of glands or the submaxillary nodes. This nerve sends twigs to the upper portion of the platysma, the depressor labii inferioris, and the risorius. Injury to this important nerve, which gives rise to temporary drooping at the angle of the mouth, must be avoided by dividing the platysma transversely on a level with the hyoid bone, fully 1 inch behind the angle of the jaw, and by dissecting the muscle with the upper flap of skin so that the nerve

is carried with this flap. When the hypoglossal nerve is severed there will be atrophy of the corresponding half of the tongue, which is protruded towards the injured side. It is surprising how well compensated this injury may be.

(9) *Results of Surgical Treatment.* The carefully followed-up cases of a large number of experienced surgeons have shown that a complete cure may be expected in over 90 per cent of the localised cases. For instance, in 1420 operations, John Fraser, one of the greatest authorities on this subject, had only 17 patients who returned for minor secondary operations. The best results are obtained in cases which come early for treatment before caseation is marked. The scar in such cases is hardly noticeable because extensive resection is unnecessary and complete excision is possible. If operation is undertaken before the appearance of sinuses and abscesses, recurrence is rare. If these complications are present and radical surgery is undertaken, it is obvious that the chances of complete cure are not so good; but, nevertheless, with modern technique and improved methods of carefully regulated doses of X-rays, the combination of surgery and radio-therapy for such cases offers good results. The operative mortality for excision of tuberculous glands in the neck is less than 1 in 2000. A few patients will die of post-operative pneumonia, which is preventable; from dissemination of the disease (miliary tuberculosis); from phthisis; or from tuberculous meningitis; but in the writer's experience such fatalities are happily unknown.

Excision of Individual Groups of Cervical Lymph Glands

(1) *Mastoid or Post-Auricular Glands.* These glands lie upon the upper part of the sterno-mastoid muscle over the mastoid process. They drain the adjoining area of the scalp, the back of the pinna, and the external auditory meatus, while their efferents drain into the upper deep cervical group. A transverse incision is made just behind the ear, over the swollen nodes, which are then dissected out. Nothing of importance will be divided except perhaps the posterior auricular vein or some twigs of the great auricular nerve.

(2) *The Pre-Auricular Gland and the Parotid Glands.* The pre-auricular gland lies immediately in front of the tragus, the situation being so constant that a swelling not exactly in front of the tragus cannot arise from this gland. The gland lies superficial to the parotideo-masseteric fascia, i.e. the fascia covering the parotid salivary gland. It drains the outer surface of the ear and the adjoining area of the scalp. The parotid glands are situated both in the superficial portion of the

parotid salivary gland and deep to it, i.e. between it and the side wall of the pharynx. The superficial glands drain the eyelids, the front of the scalp, the external auditory meatus, and the tympanic cavity. The deep glands receive lymph from the naso-pharynx and the back of the nose. The transverse facial vessels are on a superior plane under the zygomatic arch, while Stensen's duct is anteriorly placed and on a much deeper plane. The facial nerve is situated below and at a deeper level than the glands. The pre-auricular gland is removed through a small transverse incision immediately in front of the tragus (fig. 2253). *The greatest care must be taken in dissecting out the parotid lymph glands on account of the proximity of the branches of the facial nerve.*

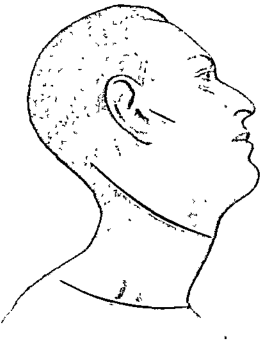

Fig. 2253 —Incisions employed for excision of tuberculous glands. The uppermost incision is used for dissecting out the pre-auricular gland. The lower two are employed for clearing out the upper and lower deep cervical groups of glands respectively.

A few twigs of the great auricular nerve will always be cut. In certain cases where there has been considerable suppuration of these glands with marked peri-adenitis, it is better to shell out the involved glands from their capsule rather than to dissect them out entire.

(3) *Occipital Glands.* These comprise two or three small glands which lie at the apex of the posterior triangle, midway between the mastoid process and the external occipital protuberance. They receive lymph from the posterior part of the scalp and are commonly enlarged and tender in pediculosis, eczema, or impetigo of the area which they drain. As the glands lie near the great occipital nerve they may, when they enlarge in tuberculous disease, press upon the nerve and cause neuralgia in the distribution of the nerve. These glands should be

removed by making a transverse incision over the anterior border of the trapezius, high up near the base of the skull. The great occipital nerve and the occipital artery are situated beneath the deep fascia on a deeper plane than the glands, and are not likely to be injured. The occipital vein, however, which is more superficial, will usually be divided.

(4) *Superficial Cervical Glands.* These glands lie in the superficial fascia around the external jugular vein on the outer surface of the sterno-mastoid muscle. They drain the parotid region and the lower part of the pinna. They are best removed through a transverse incision

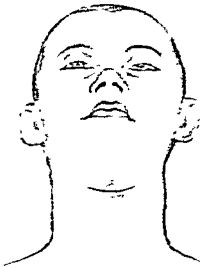

Fig. 2254.—Incisions used for removal of submental glands.

placed in one of the creases of the neck. If the superficial glands lower down are simultaneously involved, these also should be excised through a similar incision.

(5) *Submental Glands.* The glands here lie in the submental triangle on the deep fascia covering the mylo-hyoid muscle. The mylo-hyoid artery and nerve are situated on a deeper plane than the glands which drain the tip of the tongue, the central portion of the lip, and the floor of the mouth. The submental vein and the tributaries of the anterior jugular vein are necessarily divided when these glands are being excised. The incision usually employed for the dissection of these glands is a small transverse one placed midway between the point of the jaw and the hyoid bone (fig. 2254), or preferably just above the hyoid bone. Vertical incisions in this situation are to be deprecated, as they leave ugly scars.

(6) *Submaxillary Lymph Glands.* Most of the lymph glands in this region lie in the groove between the submaxillary salivary gland and the mandible, but some of them are embedded in the substance of the salivary gland itself. These glands drain the inner side of the eye, the cheek, the angle of the mouth, the side of the nose, the whole of the upper lip, the outer part of the lower lip, the gums, and a certain

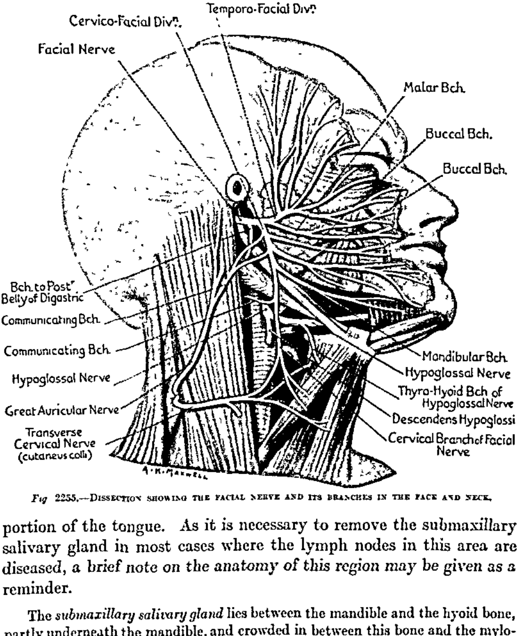

Fig 2255.—Dissection showing the facial nerve and its branches in the face and neck.

portion of the tongue. As it is necessary to remove the submaxillary salivary gland in most cases where the lymph nodes in this area are diseased, a brief note on the anatomy of this region may be given as a reminder.

The *submaxillary salivary gland* lies between the mandible and the hyoid bone, partly underneath the mandible, and crowded in between this bone and the mylo-hyoid muscle. Superiorly, it abuts on the mylo-hyoid line ; inferiorly, it is limited by the bellies of the digastric muscle ; posteriorly, it extends to the angle of the mandible, and is separated from the parotid salivary gland by fascia ; anteriorly, it reaches to a point corresponding to the mental foramen. It is the infero-lateral

removed by making a transverse incision over the anterior border of the trapezius, high up near the base of the skull. The great occipital nerve and the occipital artery are situated beneath the deep fascia on a deeper plane than the glands, and are not likely to be injured. The occipital vein, however, which is more superficial, will usually be divided.

(4) *Superficial Cervical Glands.* These glands lie in the superficial fascia around the external jugular vein on the outer surface of the sterno-mastoid muscle. They drain the parotid region and the lower part of the pinna. They are best removed through a transverse incision

Fig. [illegible].—Incision used for dissection of submental glands.

placed in one of the creases of the neck. If the superficial glands lower down are simultaneously involved, these also should be excised through a similar incision.

(5) *Submental Glands.* The glands here lie in the submental triangle on the deep fascia covering the mylo-hyoid muscle. The mylo-hyoid artery and nerve are situated on a deeper plane than the glands which drain the tip of the tongue, the central portion of the lip, and the floor of the mouth. The submental vein and the tributaries of the anterior jugular vein are necessarily divided when these glands are being excised. The incision usually employed for the dissection of these glands is a small transverse one placed midway between the point of the jaw and the hyoid bone (fig. [illegible]), or preferably just above the hyoid bone. Vertical incisions in this situation are to be deprecated, as they leave ugly scars.

(6) *Submaxillary Lymph Glands.* Most of the lymph glands in this region lie in the groove between the submaxillary salivary gland and the mandible, but some of them are embedded in the substance of the salivary gland itself. These glands drain the inner side of the eye, the cheek, the angle of the mouth, the side of the nose, the whole of the upper lip, the outer part of the lower lip, the gums, and a certain

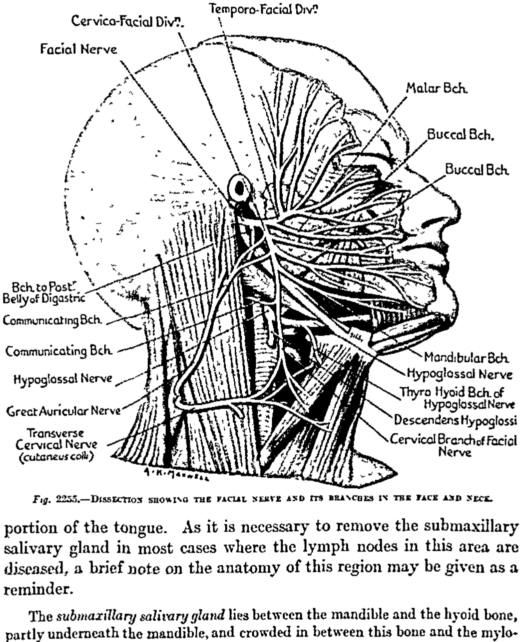

Fig. 2255.—Dissection showing the facial nerve and its branches in the face and neck.

portion of the tongue. As it is necessary to remove the submaxillary salivary gland in most cases where the lymph nodes in this area are diseased, a brief note on the anatomy of this region may be given as a reminder.

The *submaxillary salivary gland* lies between the mandible and the hyoid bone, partly underneath the mandible, and crowded in between this bone and the mylo-hyoid muscle. Superiorly, it abuts on the mylo-hyoid line ; inferiorly, it is limited by the bellies of the digastric muscle ; posteriorly, it extends to the angle of the mandible, and is separated from the parotid salivary gland by fascia ; anteriorly, it reaches to a point corresponding to the mental foramen. It is the infero-lateral

surface that comes into view so readily during dissections of the glands in the neck. It is covered by skin, superficial fascia containing the platysma muscle and the cervical branch of the facial nerve, and the deep fascia. The *facial vein* crosses the gland close to its true capsule, but under cover of the deep fascia. The *facial artery* hooks forward above the stylo-hyoid and digastric muscles, producing a deep groove in the posterior portion of the submaxillary gland, to reach its lateral surface, and then proceeds downwards and forwards between the gland and the mandible to reach the lower border of the bone at the antero-inferior angle of the masseter muscle. At this point it pierces the deep fascia and runs upwards into the face. The *mandibular branch of the facial nerve* emerges from the lower end of the parotid salivary gland, pierces the deep fascia, and runs forwards below the mandible under cover of the platysma. It communicates with the transverse cervical and great auricular nerves, supplies the platysma muscle, and gives off twigs in an upward and inward direction to supply the muscles of the lower lip (fig. 2255). The *hypoglossal nerve* hooks round the external carotid artery, crosses the lingual artery, and proceeds forwards and inwards, deep to the tendinous portion of the posterior belly of the digastric muscle, where it will be seen to lie upon the hyo-glossus muscle below the deep part of the submaxillary salivary gland. This nerve lies deep to the fascia covering the hyo-glossus muscle, and should therefore be immune from injury during dissections in this part of the neck. It gives off branches to the muscles of the tongue. The *lingual nerve* lies under cover of the mandible on the hyo-glossus muscle at a much higher level than the hypoglossal nerve, and may be inadvertently severed when the submaxillary duct is being divided.

Operation. In all those cases where involved glands appear to be inseparably adherent to the submaxillary salivary gland, it is better to remove all the glands *en bloc*, including the submaxillary salivary gland itself: but where some of the superficial nodes only are diseased, the gland may be spared.

The incision commonly employed for the dissection of these glands is a curved one, starting in the mid-line between the symphysis menti and the body of the hyoid bone. From there it extends downwards to the level of the hyoid, passes outwards across the neck, and ascends along the anterior border of the sterno-mastoid muscle, to end 1 inch below the angle of the jaw. This incision is planned so as to avoid cutting across the mandibular branch of the facial nerve, the platysma being dissected upwards together with the upper flap. This incision does, however, leave a noticeable scar, and for results it cannot be compared with the alternative one—a transverse incision which is made just below the mandible in the shadow of the jaw (fig. 2256). This latter incision is deepened down to, but not through, the platysma muscle, and after ligature of all the bleeding points in the subcutaneous tissues, the upper and lower *skin flaps* are widely dissected off the underlying platysma muscle, which in this region is a comparatively thick

muscular band. The lower flap of skin is dissected downwards well below the ala of the hyoid bone, and is drawn firmly downwards with a small retractor. The platysma muscle is here carefully divided transversely, exposing the underlying deep cervical fascia. The upper edge

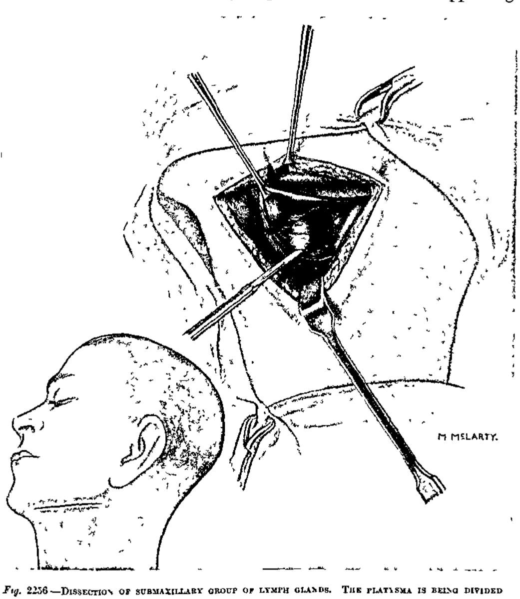

Fig. 2256.—Dissection of submaxillary group of lymph glands. The platysma is being divided low down to avoid the mandibular branch of the facial nerve.

(*Inset*) Incision placed in the shadow of the jaw. This incision extends only down to the platysma. After mobilising the skin flaps and retracting the lower edge firmly downwards, the platysma muscle is divided transversely low down in the neck to avoid injuring its nerve supply.

of the cut platysma muscle is seized with Allis forceps and retracted upwards to permit of this flap of muscle being dissected free from the underlying glandular mass, at the same time preserving its nerve supply and not in any way damaging the slender nerve twigs to the angle of the mouth.

The excision of the glands should now be undertaken after the deep cervical fascia has been freely incised. After the surgeon has tied the facial vessels, the submaxillary salivary gland with all the involved lymph nodes is dissected off the bellies of the digastric muscle and from the muscular floor of the triangle, i.e. from the mylo-hyoid, the hyo-glossus, and the superior constrictor. When the dissection reaches the border of the mandible, the facial vessels are tied at the lower edge of the bone at the antero-inferior angle of the masseter, where it is seen to pierce the deep fascia and bend upwards into the face. The greatest care must be taken in removing the deep part of the submaxillary gland and in tying off Wharton's duct, as the lingual nerve which crosses the duct may here be in danger of being injured. The hypoglossal nerve is at a lower level, lying on the hyo-glossus muscle above the hyoid bone, and is covered by fascia and the tendons of the digastric and stylo-hyoid muscles. It should not be injured if its position in relation to the deep part of the submaxillary gland and duct is remembered. In certain instances it may be advisable to remove the submental glands if they appear in the medial portion of the wound.

The wound is closed with the utmost care, the cut edges of the platysma muscle being approximated with closely applied interrupted sutures of the finest catgut, introduced with the greatest precision, and the skin edges neatly united with interrupted sutures of horse-hair or fine silkworm-gut.

Excision of the Upper Deep Cervical Group of Glands

The incision should always be generous so as to afford access to both the anterior and the posterior groups, and so as to permit of a radical removal of all the infected glands in this region. It should be so planned that it lies in one of the natural creases of the neck, and should commence at the *anterior border of the trapezius near the base* of the skull, and proceed obliquely downwards and forwards to finish in the middle line of the neck close to the upper border of the thyroid cartilage. It should likewise be below the tip of the mastoid process, and should not approach nearer than one finger's breadth to the angle of the jaw, lest the important cervical branch of the facial nerve be severed. The *incision is deepened for the whole length of the wound*, the platysma is divided, and the skin flaps with the adherent platysma are freely dissected in an upward and downward direction (fig. 2257). After all bleeding points have been ligatured, tetra-cloths are affixed to the skin edges, and the wound is then kept widely open by means of a Joll self-retaining thyroid retractor.

The sterno-mastoid (covered by deep fascia) will now be exposed, with the external jugular vein running vertically downwards over it, and the superficial nerves, i.e. the transverse cervical, the great auricular, and the small occipital, will be displayed near the middle of the posterior border of this muscle. A long segment of the external jugular vein (*together with any adjacent superficial glands*) *should* be excised, but an attempt should be made to spare the superficial nerves —in particular, the great auricular nerve, in view of its sensory supply to the side of the face. The anterior border of the sterno-mastoid is

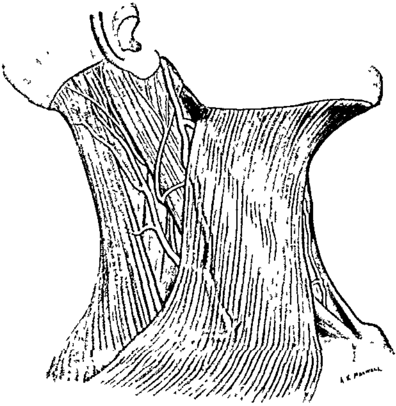

Fig 2257.—THE PLATYSMA MUSCLE.

now defined, a vertical incision is made through the deep fascia at the anterior border of this muscle, and the deep surface of the muscle is dissected off its sheath. If the muscle is infiltrated with tuberculous material, the infected portion must be excised. An effort should next be made to identify the internal jugular vein above and below the mass, after the sterno-mastoid has been firmly retracted backwards. The anterior group of glands is then dissected from the submaxillary salivary gland, and from the posterior belly of the digastric muscle above and the omo-hyoid below.

After the common facial vein has been ligatured, the glands are *separated* from the deep structures—the carotid sheath, and the middle

The excision of the glands should now be undertaken after the deep cervical fascia has been freely incised. After the surgeon has tied the facial vessels, the submaxillary salivary gland with all the involved lymph nodes is dissected off the bellies of the digastric muscle and from the muscular floor of the triangle, i.e. from the mylo-hyoid, the hyo-glossus, and the superior constrictor. When the dissection reaches the border of the mandible, the facial vessels are tied at the lower edge of the bone at the antero-inferior angle of the masseter, where it is seen to pierce the deep fascia and bend upwards into the face. now defined, a vertical incision is made through the deep fascia at the anterior border of this muscle, and the deep surface of the muscle is dissected off its sheath. If the muscle is infiltrated with tuberculous material, the infected portion must be excised. An effort should next be made to identify the internal jugular vein above and below the mass, after the sterno-mastoid has been firmly retracted backwards. The *anterior group of glands* is then dissected from the submaxillary salivary gland, and from the posterior belly of the digastric muscle above and the omo-hyoid below.

After the common facial vein has been ligatured, the glands are separated from the deep structures—the carotid sheath, and the middle

and inferior pharyngeal constrictors. As the glands are stripped off the internal jugular vein in an upward direction, the spinal accessory nerve should be identified and cleared, after which dissection on a more superficial plane is carried out up to the lower portion of the parotid gland. The main trunk of the facial nerve issuing from the stylo-mastoid foramen lies above the posterior belly of the digastric muscle, but considerably further forwards near the mandible. The cervical division of the facial nerve, however, lies in the lowest portion of the parotid gland. covered by dense fascia, and is in danger of being cut in the dissection which is necessary when the masses have to be freed in this area. It should be remembered that, as the dissection proceeds in the upper part of the carotid triangle, the main mass of glands overlies the hypoglossal nerve, the occipital artery, and the internal and external carotid arteries, as well as the internal jugular vein.

In the majority of cases the glands will easily strip away where they are not adherent to the internal jugular vein, particularly after the sheath has been divided. If, however, they are firmly adherent to the vein, it will be necessary to resect a portion of the vessel in order to facilitate their removal. Owing to the many tributaries which join the vein in its upper part and render its isolation very difficult, it is better to divide the vein *inferiorly* and to dissect it upwards rather than the reverse. A lateral ligature to a wounded portion of the vein wall is not advised. as it is so prone to be forced off during post-operative vomiting. It is far better in such cases to divide the vein completely across and to tie both ends securely.

At an early stage of the dissection the spinal accessory nerve must be sought for. displayed, and freed from the glands. The nerve will be seen to enter the deep surface of the sterno-mastoid muscle from behind the posterior belly of the digastric muscle, approximately 1–1½ inches below the tip of the mastoid process. The sterno-mastoid branch of the occipital artery is a good guide to the nerve, as it runs to the muscle superficial to the nerve. If glands are felt in the posterior triangle, the deep fascia at the posterior border of the sterno-mastoid should be divided. and, after the muscle has been retracted forwards and inwards, the freed mass of glands in the anterior triangle is drawn into this area so that both groups of glands may be completely excised together. It is advisable to keep the surface marking of the spinal accessory nerve well in mind during the dissection of the posterior group of glands, as the enlarged nodes are apt to alter the course of the nerve, and considerable risk of injury is entailed if a prolonged and determined search for it is made amongst them. The nerve emerges about the middle of the

posterior border of the sterno-mastoid, and proceeds downwards and outwards, finally disappearing under the anterior edge of the trapezius muscle. The muscular branches of the third and fourth cervical nerves are often the main supply of the trapezius, and run below the spinal accessory nerve. They may be large, in fact individually larger than the spinal accessory nerve itself, for which they may be mistaken. When the spinal accessory nerve has been found, it is drawn aside, and the glands are then stripped from the back of the internal jugular vein.

Finally, the glands are dissected from the muscles of the posterior triangle, and after the small group that hides between the levator scapulæ and the splenius capitis has been freed, the whole glandular mass with its surrounding fibro-fatty envelope is removed. Hæmostasis is then assured, the platysma carefully sutured, drainage provided, and the skin edges accurately approximated.

Excision of the Lower Deep Cervical Group of Glands

These glands are removed through a curved incision which is made about two inches above the clavicle, commencing at the anterior border of the trapezius muscle and proceeding forwards to the middle line of the neck about 1 inch above the supra-sternal notch. The terminal part of the external jugular vein will be cut and tied at the posterior border of the sterno-mastoid muscle where it pierces the deep cervical fascia.

The descending, fan-like supra-clavicular nerves of the neck will likewise be divided. The incision is deepened and the deep fascia is divided transversely at the same level for the whole length of the wound. In order to expose the glands more clearly, the clavicular head of the sterno-mastoid muscle is divided about 1 inch above the clavicle and retracted inwards. Some surgeons, however, do not consider it advisable to divide the prevertebral fascia; in fact, without doing so, the glands can easily be removed, with no fear of damaging the phrenic nerve, the nerve of Bell, or the slender twigs which supply the rhomboid and the levator scapulæ muscles, all of which lie behind this strong fascial curtain.

The spinal accessory nerve should be identified and protected where it crosses the upper part of the incision and where it will be seen to lie on the levator scapulæ (fig. 2258). The posterior belly of the omo-hyoid is then sought for, and the fascia which binds it to the clavicle is divided, after which the glands are dissected from the floor of the posterior triangle in an upward direction. The fascia covering the

anterior border of the sterno-mastoid muscle is divided, and this muscle is retracted forwards and outwards to allow the freed glands to be drawn underneath it. The omo-hyoid muscle is drawn upwards and, after the transverse cervical and supra-scapular vessels have been

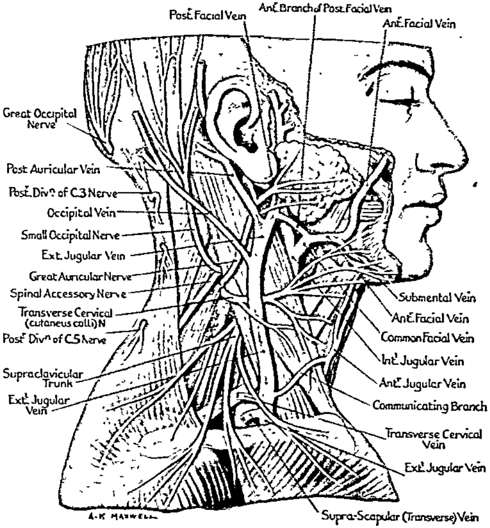

Fig. 2258.—The superficial nerves and veins of the neck.

tied, the glandular mass is forcibly drawn upwards and inwards in order to expose the main brachial nerve trunks.

The glands are now dissected off the internal jugular vein which lies deep to them. The vagus nerve lies behind the internal jugular vein in front of the vertebral vein, and will not be injured if the operator keeps the point of the knife close to the capsule of the glands, even when the involved glands extend behind this important vein.

While dissection is being carried out in this portion of the left

side of the neck, the white beaded thoracic duct will be seen, and should be protected from injury. *In those cases where all the cervical glands* on one side of the neck have to be removed through two transverse incisions, after the upper glands have been dissected free, they are drawn into the lower incision, and after the lower glands have been freed, the whole mass of glands is taken away *en bloc.*

CHAPTER IV

The Dissemination of Malignant Disease

by

W. Sampson Handley

LYMPHATIC ANATOMY

A knowledge of lymphatic anatomy is an essential part of the equipment of the surgeon or the radiologist who has to deal with malignant disease. The reader is specially referred to Sappey's great work, *Les Vaisseaux Lymphatiques*, with its beautiful plates, to Leaf's translation of Poirier, Cuneo and Delamere's work, *The Lymphatics* (Constable, 1903), or to H. Rouvière's larger and more recent book, *Anatomie des Lymphatiques de l'Homme* (Paris, Masson, 1932).

It will be necessary to refer here to certain anatomical facts concerning the lymphatic system which are important in dissemination, though they are usually ignored in anatomical text-books.

Visceral Lymphatic Anatomy.

Each of the viscera has its own complex lymphatic system. It is a fact of capital importance in dissemination that underlying the pleura and peritoneum are rich subserous lymphatic plexuses co-extensive in area with the serous membranes and forming an easy highway for permeation. The subserous lymphatic plexuses are in communication through the muscular parietes with the great fascial lymphatic plexus to be later described. The meninges, though often said to be free from lymphatics, present a rich subdural plexus which must facilitate the spread of secondary cerebral deposits.

Parietal Lymphatic System.

In the parietes the lymphatic arrangements are relatively simple, and are of great surgical interest owing to the frequency of cancer of the skin and of its appendage—the mamma.

Fascial Lymphatic Plexus.

In the deeper layer of the subcutaneous fat, lying upon the deep fascia, is a rich lymphatic plexus—the fascial plexus, which forms a network, close-meshed in some parts such as the palm of the hand, more open in the less vascular regions (fig. 2259). This plexus is a single unity, a complete network of fine channels investing the entire

body, and is the main highway for the spread of parietal cancer. Beneath the breast the fascial plexus has received the special name of the pectoral lymphatic plexus. The middle line does not interrupt the continuity of the fascial plexus.

Efferents of the Fascial Plexus.

Arising from the fascial plexus and running in the subcutaneous fat are lymphatic trunks which convey its lymph to the lymphatic glands, cervical, axillary, or inguinal. These trunks are special to particular regions, between which the only lymphatic connection is provided by

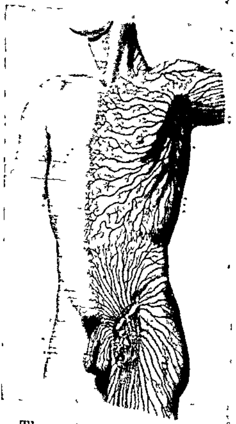

Fig 2259.—FROM A PLATE IN SAPPEY'S "VAISSEAUX LYMPHATIQUES," SHOWING THE LYMPHATIC PLEXUS (FASCIAL LYMPHATIC PLEXUS), WHICH LIES IN THE DEEPEST LAYER OF THE SUBCUTANEOUS FAT, AND FORMS *THE MAIN HIGHWAY FOR PERMEATION* IN CANCER AFFECTING THE PARIETAL TISSUES *AND FOR LYMPHATIC INFECTIONS* NUMEROUS TRUNKS ARE SEEN ARISING FROM THE PLEXUS AND PASSING TO THE AXILLARY OR THE INGUINAL GLANDS ALONG THESE TRUNKS EMBOLIC INVASION OF THE AXILLARY GLANDS OCCURS, THE TRUNKS THEMSELVES ESCAPING PERMEATION UNTIL A LATE STAGE. (*By kind permission of Messrs Kegan Paul, from Handley's "Genesis of Cancer"*)

the continuity of the fascial plexus. The parietes are thus divided into six lymphatic areas, three on each side. The two horizontal planes which separate these areas run round the body at the level of the clavicle and the umbilicus respectively.

Embolic invasion of lymphatic glands is restricted to the glands of the particular area in which the cancer originates, unless, by permeation through the fascial plexus, cancer-cells have transgressed the boundary zone and reached another lymphatic area. Lymphatic embolism across the boundaries of a lymphatic area is not possible. A knowledge of these simple facts makes it possible to say what glands must be removed or radiated for a superficial growth in any given position. Thus for

and cutaneous secondary nodules frequently occur, the intervening skin may show no sign of cancer. Such nodules are to be regarded as isolated "efflorescences" from the infected fascial lymphatic plexus beneath. The area of infected fascia is always larger than the area of skin showing nodules, a fact of great surgical importance.

Muscular Lymphatics.

Tributaries from the underlying muscles run into the fascial plexus on its deep aspect. The muscular lymphatics in turn communicate with the subserous plexuses. These fine anastomotic connections enable cancer-cells from superficial cancers to reach the cœlomic cavities. Sometimes, on the other hand, the cells of visceral cancers may thus reach the fascial plexus and may produce subcutaneous nodules.

Concomitance of Lymphatic Vessels and Blood-vessels.

Just as gas, water and electric mains often run in the same conduits, so in the body an artery, one or two veins and two lymphatic vessels are normally found in company, and this fact has important consequences, for the rupture of a cancerous lymphatic may initiate infiltration round the concomitant vessels with ultimate invasion of the venous or arterial lumen. In melanotic sarcoma I have traced all stages of this process. It probably also occurs in late stages of carcinoma.

Initial Obstacles to Dissemination.

It is to be noted that at first the cancer-cells have no access to the vessels either of the lymphatic or of the hæmic system. The hæmic system is, of course, a completely closed one. The lymphatic vessels also form a closed system which does not communicate with the tissue interspaces. The lymphatic capillaries begin as closed sacs of endothelium which unite to form lymphatic vessels, and these to form larger lymphatic vessels, which, after passing through a series of filter-beds—the lymphatic glands—empty into the venous system by the thoracic duct, the right lymphatic duct and, according to Leaf, by a communicating vessel in the groin.

It is further to be noted that according to my observations (*Genesis of Cancer*, Kegan Paul, 1931), pre-cancerous areas are areas in which the lymphatics have been destroyed by previous attacks of obliterative lymphangitis. Permeation can only begin when the infiltrating cancer-cells reach patent lymphatic vessels. Hence the primary growth usually attains a considerable size before enlargement of the glands indicates that lymphatic spread has begun. If the area of pre-cancerous obliteration of the lymphatics is a very large one, as, for instance, in lupus-cancer, dissemination is usually prevented, however locally malignant the disease may be.

instance, for a growth at the right margin of the anus, or on the right lower extremity, or on the right side of the back below the level of the umbilicus, only the right inguinal glands will need removal. In an early cancer of the breast only the homolateral glands will be affected, but as soon as permeation crosses the middle line, embolic infection of the glands of the contralateral axilla occurs.

If a growth starts at the junction of two lymphatic areas two sets of glands will need removal. For example, in a squamous-celled carcinoma in the middle line below the umbilicus, both sets of inguinal glands must be removed. A similar growth at the level of the umbilicus

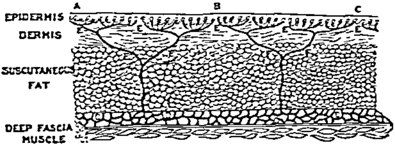

Fig. 2260.—To show the lymphatic arrangements of the skin. A schematic vertical section of the skin and subcutaneous fat, with a small horizontal shelf of deep fascia projecting forward from it. Below this is muscle in vertical section. AB and BC are two of the primary lymphatic areas of the skin. These areas measure one-third to half an inch in diameter, and the only lymph-vascular communication between them appears to be by way of the subjacent fascial lymphatic plexus DDDD, which is seen on the flap. The lymphatic end-sacs of the skin papillæ unite by groups of five or six to form small lymphatic vessels, which again unite in the superficial third of the dermis (plane of primary confluence EEE) to form other lymphatic vessels which pierce the dermis vertically and unite just beneath it (plane of secondary confluence FFF) into a smaller number of vessels which run down through the subcutaneous fat to discharge into the fascial lymphatic plexus DDD.

(Reproduced from the Author's "Genesis of Cancer," Kegan Paul, 1931)

and to the right of it would infect the axillary and inguinal glands of the right side. A growth actually at the umbilicus would simultaneously invade the axillary and the inguinal glands of both sides.

Lymphatic Anatomy of the Skin.

The basic fact in the minute lymphatic anatomy of the skin is that each papilla has as its central structure a minute capillary lymphatic end-sac, the same arrangement being seen in the intestinal villus. Groups of these end-sacs unite to form lymphatic vessels in the superficial third of the dermis and then continue vertically through the subcutaneous fat to join the fascial plexus (fig. 2260).

The skin appears to be divided into small lymphatic areas of $\frac{1}{3}$—$\frac{1}{2}$ an inch in diameter, between which there is little communication except by way of the underlying fascial plexus. It results that cancer has little tendency to spread in the plane of the skin. Though subcutaneous

and cutaneous secondary nodules frequently occur, the intervening skin may show no sign of cancer. Such nodules are to be regarded as isolated "efflorescences" from the infected fascial lymphatic plexus beneath. The area of infected fascia is always larger than the area of skin showing nodules, a fact of great surgical importance.

Muscular Lymphatics.

Tributaries from the underlying muscles run into the fascial plexus on its deep aspect. The muscular lymphatics in turn communicate with the subserous plexuses. These fine anastomotic connections enable cancer-cells from superficial cancers to reach the cœlomic cavities. Sometimes, on the other hand, the cells of visceral cancers may thus reach the fascial plexus and may produce subcutaneous nodules.

Concomitance of Lymphatic Vessels and Blood-vessels.

Just as gas, water and electric mains often run in the same conduits, so in the body an artery, one or two veins and two lymphatic vessels are normally found in company, and this fact has important consequences, for the rupture of a cancerous lymphatic may initiate infiltration round the concomitant vessels with ultimate invasion of the venous or arterial lumen. In melanotic sarcoma I have traced all stages of this process. It probably also occurs in late stages of carcinoma.

Initial Obstacles to Dissemination.

It is to be noted that at first the cancer-cells have no access to the vessels either of the lymphatic or of the hæmic system. The hæmic system is, of course, a completely closed one. The lymphatic vessels also form a closed system which does not communicate with the tissue interspaces. The lymphatic capillaries begin as closed sacs of endothelium which unite to form lymphatic vessels, and these to form larger lymphatic vessels, which, after passing through a series of filter-beds—the lymphatic glands—empty into the venous system by the thoracic duct, the right lymphatic duct and, according to Leaf, by a communicating vessel in the groin.

It is further to be noted that according to my observations (*Genesis of Cancer*, Kegan Paul, 1931), pre-cancerous areas are areas in which the lymphatics have been destroyed by previous attacks of obliterative lymphangitis. Permeation can only begin when the infiltrating cancer-cells reach patent lymphatic vessels. Hence the primary growth usually attains a considerable size before enlargement of the glands indicates that lymphatic spread has begun. If the area of pre-cancerous obliteration of the lymphatics is a very large one, as, for instance, in lupus-cancer, dissemination is usually prevented, however locally malignant the disease may be.

Proliferation-pressure of Cancer-cells.

The dissemination of cancer is an effect of the ceaseless tendency to proliferate, which is a fundamental property of the cancer-cell. The proliferating masses of cells are forced quasi-mechanically along the

Fig. 2261.—× 150. A permeated lymphatic in longitudinal section with normal blood-vessels above and below it.

Fig. 2262.—A permeated lymphatic in transverse section. A small branch lymphatic not yet invaded is seen running into it. Distension of the lymphatic has not yet begun. Note the absence of round-celled infiltration.

Fig. 2263.—A permeated lymphatic beginning to be distended by the cancer-cells within it. The cancer-cells are swollen and show signs of incipient degeneration.

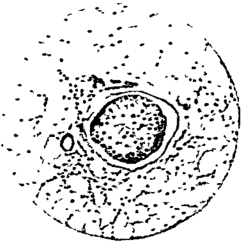

Fig. 2264.—A permeated lymphatic distended almost to the point of rupture. The cancer-cells are degenerate, and round-celled infiltration of the peri lymphatic tissues is beginning.

lines of least resistance. Rupture of the basement membrane gives the cancer-cells access to the intercellular spaces of the adjacent connective tissue, and their local spread through these spaces by infiltration forms the primary growth.

Invasion of the Vascular Systems.

The high pressure developed by infiltration at the site of the primary growth, and the erosive or digestive action of the cancer-cells upon the contiguous normal tissue, ultimately give the cancer-cells access to the lymphatic capillary system and also, though usually at a much later date, to the blood-vessels.

Permeation.

When cancer-cells enter a lymphatic capillary they find an open lumen along which they can easily grow as a continuous line or tendril of cells. I described this process in 1904 and named it *permeation* (figs. 2261 to 2269). At a certain stage in the formation of the primary

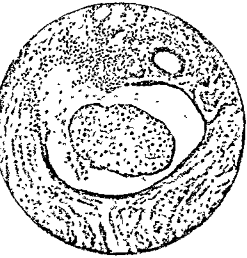

Fig. 2265.—RUPTURE OF A DISTENDED PERMEATED LYMPHATIC BY THE INCLUDED CYLINDER OF CANCER CELLS. INTENSE ROUND-CELLED INFILTRATION AND TRAUMATIC HÆMORRHAGE HAVE RESULTED FROM THE RUPTURE.

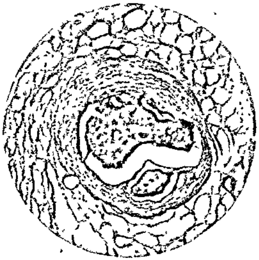

Fig. 2266.—SHOWS THE PROCESS OF PERI-LYMPHATIC FIBROSIS WHICH FOLLOWS RUPTURE OF A PERMEATED LYMPHATIC. THE CANCER-CELLS, NOW COMPLETELY DEGENERATE, ARE ENCLOSED IN A CAPSULE OF NEWLY FORMED FIBROUS TISSUE.

growth, the small lymphatics of the surrounding tissues beyond its infiltrating edge are permeated and the dissemination of the growth has begun.

Fate of Permeated Lymphatics.

It is quite difficult to find evidence of permeation in the tissues round the primary growth, unless the search is a systematic one. A permeated lymphatic is not a permanent structure. The proliferation of the contained cancer-cells distends and finally splits up the lymphatic vessel (figs. 2264 and 2265). Before rupture occurs, the internal pressure has so damaged and devitalised the cancer-cells that the vigorous inflammatory reaction which follows on the rupture, and the fibrosis which ensues, are able to destroy the cancer-cells. I have traced every stage of this process, which may be called *peri-lymphatic fibrosis* (figs.

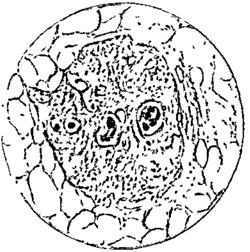

Fig. 2267.—THE PENULTIMATE STAGE OF PERI-LYMPHATIC FIBROSIS. THE ORIGINAL LYMPHATIC IS REPRESENTED BY A SOLID THREAD OF FIBROUS TISSUE CONTAINING REMAINS OF CANCER-CELLS. IN THE FINAL STAGE ALL TRACE OF CANCER-CELLS DISAPPEARS.

Fig. 2268.—×75. PERMEATED LYMPHATICS OF VARYING CALIBRES FROM A CASE OF BREAST CANCER. (*The Bland Sutton Pathological Institute, Middlesex Hospital.*)

Fig. 2269.—×430. THE PERMEATED LYMPHATIC SEEN AT A IN THE PRECEDING FIGURE MORE HIGHLY MAGNIFIED. NOTE THE ENDOTHELIAL LINING AND THE ABSENCE OF A MUSCULAR COAT. CENTRAL DEGENERATION OF THE CYLINDER OF CANCER CELLS IS BEGINNING. (*Photo, the Bland Sutton Institute.*)

2266 and 2267). It is a locally curative process, but, for reasons which a little consideration will make obvious, it is quite incompetent to arrest the spread of the cancer. It always occurs just too late, since the distension of the lymphatic which is preliminary to rupture and fibrosis forces the cancer-cells still further afield, into hitherto intact regions of the lymphatic network.

The Microscopic Growing Edge.

At a certain stage in the progress of the growth, and beyond its infiltrative growing edge, there is a devastated area, apparently normal to the naked eye, in which the permeated lymphatics have undergone fibrosis and have been replaced by solid threads of fibrous tissue. In this area there may be found here and there isolated microscopic secondary nodules of cancer, due to the sporadic and local failure of the protective process of peri-lymphatic fibrosis. Though apparently isolated, these nodules have arisen in continuity with the primary growth as terminal outcrops of the insidious process of permeation.

Beyond this devastated area a careful search may detect the real microscopic edge of the growth—a zone of permeated lymphatics a few millimetres wide. Here, distension, rupture and fibrosis are absent and there is no round-celled infiltration.

The gradual spread of permeation through the tissues is comparable to the spread of a ringworm from its point of origin. On any old tombstone with its lichens, or on the fireback with its spreading circles of incandescent soot, a similar process may be seen. In cancer it is invisible and can only be traced laboriously by the microscope, but sometimes it is clinically manifested in the centrifugal spread of a crop of subcutaneous nodules (see fig. 2270).

Epigastric Invasion of the Abdomen in Breast Cancer.

In breast cancer, permeation of the fascial plexus in the region of the ensiform cartilage frequently leads to permeation of the subperitoneal lymph plexus of the underlying parietal peritoneum. Transcœlomic implantation next produces nodules upon the adjoining upper surface of the liver, while at the same time cancer-cells fall into the pelvis and produce ovarian secondary deposits. Other cancer-cells may be encysted by the omentum with the production of nodular omental deposits, or may adhere to and grow upon any part of the peritoneal surface.

Invasion of the Fascial Lymphatic Plexus in Stomach Cancer.

In gastric carcinoma, permeation of the subserous lymphatic plexus over the growth may take place at an early stage, and cancer-cells soon escape into the peritoneal cavity. Transcœlomic implantation then

occurs, followed by permeation of the subserous lymphatic plexus near the site of the implantation. In the region of the umbilicus the subserous lymphatic plexus is only separated from the fascial lymphatic plexus by the linea alba, which is pierced by communicating lymphatics.

Fig. 2270.—Carcinoma of the breast in a man of thirty-eight with gynæcomastia. To illustrate the centrifugal spread of fascial permeation from its point of origin in the breast, with upstream local extensions to the skin forming cutaneous nodules.

(*Middlesex Hospital, 1930.*)

Permeation extends to the fascial plexus, and a crop of subcutaneous nodules, at first close to the umbilicus (fig. 2271), but extending centrifugally from it, may signalise the spread of permeation in the fascial plexus.

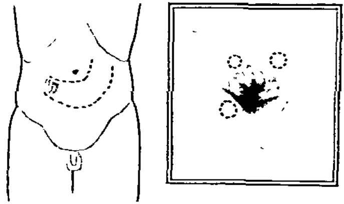

Fig. 2271.—The first stage of permeation of the fascial plexus in stomach cancer. A pyloric tumour in a man of middle age. Inset, the umbilicus, natural size, with three subcutaneous nodules, represented by dotted lines, which enabled the diagnosis of gastric carcinoma to be made with certainty.

These nodules may eventually spread up to the vertex of the skull, downwards to the middle of the thigh, and almost down to the elbow. The opposite convexities of the circle of permeation may meet in the middle of the back (fig. 2272).

A similar extreme extension of permeation in the fascial plexus is

sometimes seen in breast cancer, but here too the distal portions of the limbs escape so that blood dissemination is excluded. These extreme cases show that permeation is theoretically able to penetrate the entire body, since the finest anastomotic lymphatics offer no barrier to its advance. Fortunately, it is, as a rule, a slow process, though more rapid than infiltration.

Mode of Spread of Permeation.

Permeation begins at the edge of the primary growth and spreads away from it in a centrifugal manner, but owing to the anatomical

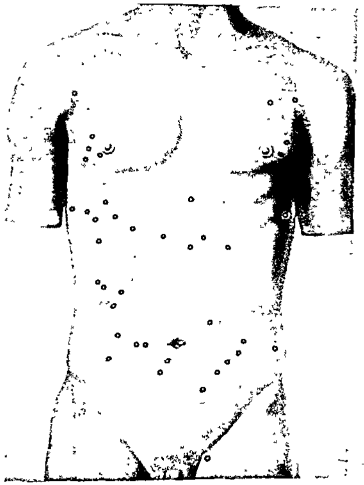

FIG 2272.—ADVANCED PERMEATION OF THE FASCIAL PLEXUS IN STOMACH CANCER. MANY OF THE ORIGINAL NODULES AROUND THE UMBILICUS HAVE DISAPPEARED.

arrangements of the lymphatic system the permeated area of tissue is not usually spherical. The process spreads most easily in the plane of the main lymphatic plexus of the part. Thus in cutaneous and mammary cancers the plane of maximal spread is the plane of the deep fascia, and this is the layer which requires the most extensive removal. But after a time cancer-cells are forced by the increasing pressure in the main plexus to grow into the little tributaries which reach it from the skin above and from the muscles beneath, and a smaller circular area of

skin and muscle is invaded. These facts are the key to operative treatment for all parietal cancers. They show that the portion removed must be accurately centred on the primary growth and that it must be circular in shape, since permeation spreads in a centrifugal manner. They indicate the necessity of removing a limited circular area of possibly infected skin around the primary growth. When this area has been marked out, thin skin flaps must be raised until a large circular area of deep fascia has been exposed for removal. This is circumscribed by a circular incision down to the muscles, and its thin edges are now raised up from the muscles, working from the periphery towards the centre of the operation field. Finally, an area of muscle subjacent to the primary growth is also removed. These are the general principles which govern equally an operation for breast cancer and one for any disseminating growth of the skin such as a melanotic sarcoma. The operation must also take into account the process of lymphatic embolism and remove the lymph glands in one piece with the primary growth, the permeated area of tissue around it, and the trunk lymphatics which run from the growth to the glands (" monobloc " operation).

Permeation around Secondary Deposits.

Not only does permeation occur round the primary growth, but also around every secondary deposit. Thus, for instance, when a lymphatic gland is invaded by lymphatic embolism its idle tributary and efferent lymphatics provide particularly easy routes for permeation of the surrounding district. This is easy to demonstrate round the inguinal glands in melanotic sarcoma of the lower extremity. The fact has surgical importance. I have shown that in melanotic sarcoma, when the inguinal glands are removed, it is essential also to remove a surrounding circular area of the deep fascia.

Trunk-Permeation.

It is but rarely that permeation of the larger lymphatic vessels can be seen by the naked eye, but figure 2273 shows it beautifully in cancer of the bowel, and cases of permeation of the thoracic duct, though rare, are well recognised.

Trunk-permeation is a late event, since for a long time the lymph stream scours out the larger vessels. In the capillary lymphatics the feeble stream has no influence on the spread of permeation which proceeds as readily against the stream as with it. Before trunk-permeation occurs, the primary growth and the infected glands may be excised separately without incurring the penalty of recurrence. Later, a " monobloc " operation is essential to prevent recurrence in the line of the trunk lymphatics.

Lymph-Gland Embolism.

Before the process of permeation has extended very far from the primary growth some of the cancer-cells will project into the lumen of a trunk lymphatic, and a new factor comes into play. In the larger lymphatics the lymph stream is strong enough to sweep away the intruding cancer-cells. They are carried to the nearest lymphatic gland and deposited in its capsular sinus.

Lymph glands act for a considerable time as a barrier to the further spread of cancer-cells which reach them. The cancer-cells proliferate through the meshes of the gland, enlarging it and finally destroying its lymphatic structure. They finally reach the efferent lymphatics of the

Fig 2273.—Retrograde permeation of trunk lymphatics of the small intestine in cancer of the prostate The largest lymphatics are seen as white moniliform lines, the smaller ones as white networks upon the surface of the intestine The specimen *shows that the valves of* the lymphatic vessels are no obstacle to the spread of permeation against the lymph current.

(*By courtesy of Mr Cecil P G. Wakley. Museum, King's College Hospital.*)

gland and may permeate along these vessels to the next set of glands. Embolism at this stage is unlikely, since the stream of lymph through a gland must cease when it is choked by cancerous growth.

The high frequency of lymph-gland enlargement as the first clinical evidence of dissemination is a conclusive proof that the earlier and surgically important stage of the process takes place usually by way of the lymphatic system. This is confirmed by the fact that if a breast cancer is removed before the axillary glands are infected, about four cases out of five remain free from recurrence. The absence of remote deposits at the time when gland enlargement first declares itself shows that at this period spread by the blood stream is a negligible factor. Were this not so, the ablation of cancer would be a hopeless enterprise.

Retrograde Lymphatic Embolism.

Some authors have asserted that retrograde lymphatic embolism

is an important factor in dissemination. For instance, in breast cancer, when the homolateral axillary glands are blocked by growth, it is assumed that the lymph stream, setting towards the opposite breast, will carry cancer-cells to the opposite axillary glands. But the presence of valves in the trunk lymphatics will prevent reflux, and the fine anastomotic plexus of the middle line in any event acts as an effective filter which cancer-cells can only pass by permeation. I have shown that no outlying embolic foci can be found outside the microscopic growing edge of a breast cancer except in the glands.

By-pass Lymphatic Trunks.

Certain trunk lymphatics may pass by the first set of glands in their course, ultimately to reach glands more remote. Thus, some of the lymphatics of the forearm avoid the bicipital gland and run direct to the axillary glands. In a recent case of multiple X-ray cancer of the fingers, the bicipital gland was free from cancer-cells, which were, however, present in one of the axillary glands.

Invasion of a Gland often precedes Clinical Enlargement.

In the case just referred to, no enlarged glands could be felt prior to operation. It illustrates the validity of the surgical principle that except in growths known not to disseminate (rodent ulcer, lupus-carcinoma, and osteoclastoma) it is essential to cut the main line of dissemination by a complete removal of the regional glands, even if these glands appear clinically normal. If age and debility forbid this ideal course, a prolonged follow-up at short intervals is essential. The radium treatment of glands has hitherto not been so successful as to compete with their surgical removal. In certain carcinomata, e.g. of the lip and tongue, radium to the primary growth and surgical removal of the glands appears to be the method of choice.

In dealing with late or specially malignant growths it may be advisable to excise not only the regional glands, but also the set higher up. This is always advisable in melanotic sarcoma. For instance, if in this disease the axillary glands are enlarged, the supra-clavicular glands, even if not enlarged, should also be removed.

Gland Invasion from different Primary Sites.

It is impossible to deal in detail with glandular invasion from every site in which a growth may arise. Certain points of special surgical importance need a brief reference.

Carcinoma of the Breast.

As soon as lymphatic dissemination begins, the obstacles to permanent success after operation are formidable, owing to the rich and complex lymphatic connections of the breast.

Internal Mammary Gland Invasion.

Upon evidence that has never been challenged, the writer showed (*Surg., Gyn., and Obst.*, December 1927, 721) that when the axillary glands are invaded by growth there is a presumption that the internal mammary glands also are invaded. The two invasions are broadly simultaneous, but in carcinoma of the inner edge of the breast, that of the internal mammary glands may actually be the earlier. It may be inferred that in the average operation case of breast cancer with enlarged axillary glands the disease is already intra-thoracic. Fortunately, though the surgical removal of the internal mammary glands is hardly practicable, they can be dealt with by radium tubes introduced when the breast is removed, a procedure which, at the end of three years, shows an improvement of 10 per cent in the non-recurrence rate.

Apical Axillary Glands.

After operative clearance of the axilla it is very rare to see axillary recurrence, provided the clearance has been complete. Unfortunately, owing to their sheltered position, the apical glands of the axilla, lying upon the first digitation of the serratus magnus internal to the axillary vein and immediately below the clavicle, frequently escape removal. It is important to know that owing to a lymphatic trunk which pierces the great pectoral muscle to reach them directly, these glands may be infected before the lower glands of the axilla.

Aortic Gland Invasion.

After invasion of the internal mammary glands the next intra-thoracic glands to be attacked are the glands in the superior mediastinum on the arch of the aorta. This hopeless stage of thoracic invasion may have been reached in cases which appear operable. While the modern operation has almost abolished local recurrence, it cannot prevent the ultimate fatal evolution of deep latent foci within the chest.

If spread from the internal mammary glands to the glands on the arch of the aorta has occurred prior to operation, it is likely that a superior mediastinal tumour, with upper sternal dullness, dysphagia, dyspnœa, pleural and pulmonary deposits, and perhaps spinal metastases, will develop after a period of apparent health. This type of recurrence is due rather to the patient's procrastination than to any defect of surgical method. Even in such cases operation justifies itself by prolonging the patient's span of normal active life, and by averting the distress of external ulceration and lymphœdema of the arm.

Supra-clavicular Gland Invasion.

The first gland above the clavicle to show enlargement in breast cancer is situated in the lower and inner angle of the posterior triangle,

or behind the clavicle. This gland has connections both with the internal mammary glands and with the apical axillary glands. Subsequently, glands lying in the omo-hyoid triangle are involved, and next the glands

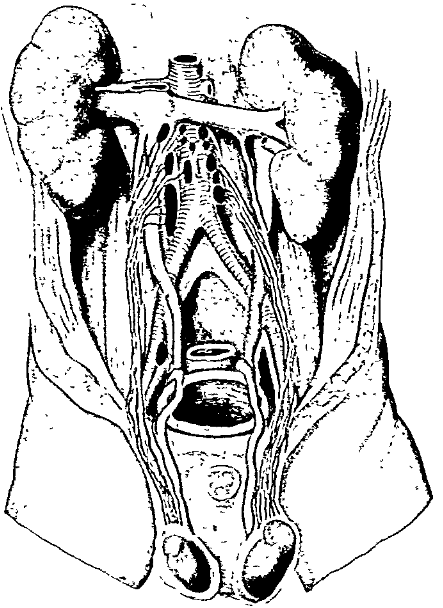

Fig. 2274.—The Lymphatics of the Testicle. ([illegible].)

of the main cervical lymphatic chain. Still later, a gland appears at the lower and inner angle of the posterior triangle of the opposite side. The evolution here repeats that on the homolateral side.

The early removal of enlarged supra-clavicular glands may avert recurrence for periods up to ten years, especially if combined with the

use of radium in the floor of the wound, and along the main cervical chain up to the base of the skull. I recently saw a case free from recurrence 22 years after such an operation.

Growths of the Testicle.

The descent of the testicle from its original position just below the kidney into the scrotum involves no change in its efferent lymphatics

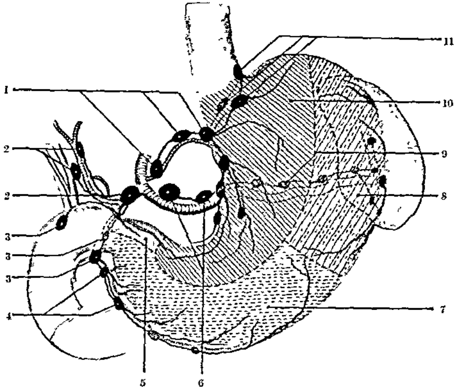

Fig 2275.—THE LYMPHATIC TERRITORIES OF THE STOMACH. (*Rouvière*)

10. *Coronary territory.*
11. Cardiac glands.

except their elongation. They continue to drain into the aortic glands at the level of the renal veins (fig. 2274).

Consequently, lymph-gland enlargement in testicular growths must be sought for in the epigastric angle at about the level of the pancreas, where a deep homolateral induration may be palpable near the middle line.

The glands subsequently affected are those upwards along the œsophagus and perhaps at the root of the neck. Thus an enlarged gland in the omo-hyoid triangle may be the first clinical indication of an unobserved testicular growth.

It is not difficult to remove the lymphatic pedicle of the testicle

in the submaxillary glands, or if they arise further back, debouch directly into the tonsillar gland. One of the anterior marginal lymphatics runs to a gland of the main chain situated lower than the tonsillar gland.

(3) *Posterior,* arising from the region where the anterior pillar of the fauces joins the tongue, run either into the tonsillar gland, or into the submaxillary glands and thence to the tonsillar gland.

(4) *Central,* coming from the interior of the tongue.

Thus, as Poirier says, the efferent lymphatics of the tongue have a lower destination, the further forward in the tongue they arise. It is even

through an external iliac incision up to the level of the renal veins, and the operation permits accurate radiation of the glands up to the diaphragm by implanted radium tubes on stout wires. In a recent case where I carried out this operation the highest gland removed was invaded by growth.

The testicle should be removed in one piece with the spermatic vessels and lymphatics. The vas deferens should be traced down into the pelvis and divided just above the bladder.

Stomach Cancer.

The lymphatic vessels of the mucosa of the stomach run to a rich subserous plexus, continuous over the whole stomach. From this plexus a series of lymphatic trunks concomitant with the gastric arteries arises and, according to the destination of these vessels, the stomach is divisible into three lymphatic regions, hepatic, splenic and coronary. The boundaries of these regions and the glands corresponding to them are indicated in H. Rouvière's diagram (fig. 2275). Cancer arising in the "splenic" area of the stomach has a better prognosis than cancer of the lesser curvature, apparently because its lymphatic connections are more restricted. It is probable that the use of buried radium tubes to deal with the glandular areas after gastrectomy would improve results. A study of figure 2275 will indicate how they should be placed.

Tongue Cancer.

It is important to know that the lymphatic vessels of the tongue decussate freely across the middle line. Jamieson and Dobson (*Brit. Journ. Surg.*, July 1920, 80) showed that only a very limited region of the tongue, namely the posterior two-thirds of the lateral margin, drains exclusively into the glands of the same side. For cancers arising anywhere else in the tongue, gland infection on both sides may be expected, and a bilateral gland operation is indicated.

The lymphatics from the various regions of the tongue, from its apex to its base, take a more or less parallel direction downwards and backwards, ultimately, after perhaps passing through intermediate glands, reaching the glands of the deep main cervical chain.

Poirier divides the collecting vessels of the tongue into four main groups (fig. 2276):

(1) *Apical*, two in number, one running direct to the sub-omo-hyoid gland low down in the main cervical chain, the other running to the submental gland.

(2) *Marginal*, coming from the lateral border and following the course either of the lingual artery or of the lingual vein, terminate

in the submaxillary glands, or if they arise further back, debouch directly into the tonsillar gland. One of the anterior marginal lymphatics runs to a gland of the main chain situated lower than the tonsillar gland.

(3) *Posterior*, arising from the region where the anterior pillar of the fauces joins the tongue, run either into the tonsillar gland, or into the submaxillary glands and thence to the tonsillar gland.

(4) *Central*, coming from the interior of the tongue.

Thus, as Poirier says, the efferent lymphatics of the tongue have a lower destination, the further forward in the tongue they arise. It is even

more important to note that early tongue cancer may infect the main lymphatic chain from the digastric to the omo-hyoid (fig. 2277). The disease spreads rapidly along the glands of the main chain. Hence

a gland operation for cancer, as Butlin showed many years ago, must extend from the base of the skull to the sterno-clavicular joint, and must remove all the glands of the main chain and those of the submaxillary triangle. It may be unilateral only if the disease has begun in the posterior two-thirds of the lateral margin. The writer would add that, in his opinion, although the exposure of the internal jugular vein in its whole length is an essential preliminary of the operation, the removal of this vein and still more of the carotid artery is a gratuitous

complication of the operation which aggravates its risks without improving its results.

Growths on the Cheek.

A recent case of melanotic sarcoma of the middle of the cheek may be taken as illustrating lymphatic spread from this situation. No enlarged glands could be felt before operation, but the operation disclosed black glands beneath the parotid fascia, in the pre-auricular region, and in the submaxillary triangle. The tonsillar gland was much enlarged, and from this gland infection had spread up and down the main lymphatic chain of the neck as high as the base of the skull, and down to the omo-hyoid.

The primary growth, its efferent lymphatics and the glands were removed in one piece by a troublesome dissection (fig. 2278) which necessarily divided some of the branches of the facial nerve. A year later the patient shows no sign of recurrence.

Rectal Growths.

Growths beginning in the anal canal below the white line, which is formed by an invagination of the skin, metastasise to the inguinal glands, usually of both sides. Rectal growths higher up first cause enlargement of the glands in the mesorectum as high as the promontory. Later, the internal or external iliac glands and the aortic glands may enlarge. Still later, by way of communicating lymphatics through the inguinal canal, the inguinal glands may be infected.

Lymphœdema in Cancer.

The blocking by permeation of large areas of the lymphatic system in cancer often leads to a lymphatic œdema of the skin (*peau d'orange*), sometimes to a massive œdema of a whole limb (*brawny arm*), and

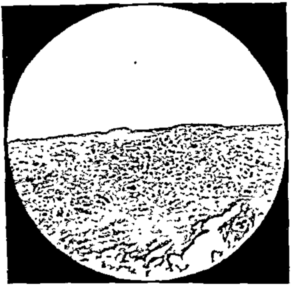

Fig. 2279.—Permeation of the subpleural lymphatic plexus (so-called lymphangitis carcinomatosa).

sometimes to a serous effusion in the pleura or peritoneum. Serous effusions appear to be the result of permeation of the subserous lymphatic plexuses by which, normally, excess serous fluid is absorbed (fig. 2279). Ascites and pleural effusion are frequent immediate causes of death in cancer.

Pressure of growth masses on veins, by increasing transudation, may aggravate lymphatic œdema. Lymphœdema does not necessarily mean that the œdematous tissue contains cancer-cells, it only implies that permeation has blocked the lymphatics somewhere between the œdematous area and the glands into which it drains.

The Relative Share of the Hæmic and Lymphatic Systems in Dissemination.

There is no doubt that cancer may spread either by the lymphatics or

by the blood stream. Naked-eye demonstration of this statement is afforded by the exceptional cases in which the inferior vena cava, or the thoracic duct, may be found plugged by growth. But in carcinoma and in melanotic sarcoma, and possibly in other sarcomata, the main highway of the disease until it is far advanced is certainly the lymphatic system, partly because access to the blood stream is more difficult, but mainly because healthy blood is a medium hostile to the life of epithelium, exciting an organising thrombosis which destroys the cancer-cells.

In the last stages of the disease the resistance of the blood to colonisation by cancer-cells may break down. Thus R. Volk described a case of gastric carcinoma which had invaded the liver. Cancerous pulmonary embolism had occurred, and daughter-nodules were found in the kidneys, in the brain, and upon atheromatous ulcers in the abdominal aorta.

Local Invasion of the Blood-Vessels in the Primary Growth.

In certain sarcomata the blood-vessels, often thin-walled and rudimentary, lie embedded in a mass of neoplastic cells, and local invasion of the blood stream must occur early, but dissemination in sarcoma has not been accurately studied, save in melanotic sarcoma, a subject which will be dealt with later.

In rare and exceptional cases of breast cancer Delbet and Mendaro have demonstrated local invasion of the blood-capillaries. In the aged, breast cancer may exceptionally first manifest itself by the sudden appearance of a hæmatoma in the breast, a proof of the erosion of blood-vessels by the growth. Such cases, however, do not at this stage present evidence of widespread dissemination. Dissemination to the bones in advanced breast cancer, without any glandular enlargement, is not unknown.

Destruction of Cancerous Emboli in the Blood Stream.

M. B. Schmidt in forty-one cases of abdominal malignant disease found fifteen cases in which cancerous emboli were present in the lungs. In seven of the fifteen cases no macroscopic deposits were found in the lungs or liver, or in the course of the systemic circulation. Only three cases showed deposits in the lungs visible to the naked eye. It may be inferred either that the embolism only occurred just before death, or that the emboli were, as a rule, destroyed promptly after reaching the blood stream. Schmidt states definitely that most of the emboli are destroyed by organisation of their ensheathing thrombus, or are encapsuled and rendered harmless.

Goldmann found that when the wall of a vein is infiltrated by

growth a protective thrombosis may occur within the vein. He also showed that invasion of the veins near the primary growth might occur in cases which were found post mortem to present no metastases.

It thus appears that invasion of the blood stream in malignant growths, though it may be frequent, is usually late and ineffective, except perhaps in some sarcomata.

Of late there has been a tendency to hark back to the embolic theory of dissemination. R. A. Willis (*The Spread of Tumours in the Human Body*, J. and A. Churchill, 1934) has recently stressed the importance of blood dissemination, basing his views on the examination of portions of tissue selected as suspicious at necropsy, and has brought forward new and interesting evidence. He found evidence of blood dissemination in 15 per cent of cases. But random sampling of the tissues cannot determine the relative shares of the blood and lymph systems in dissemination. It is necessary to adopt microscopic methods on a macroscopic scale, and to examine long strips of tissue extending radially from the primary growth into the surrounding tissues. Using this method I have shown that lymphatic permeation is the main agent in the earlier stages of dissemination. Whereas cancer-cells in a blood-vessel excite a thrombotic reaction which usually destroys them, cancer-cells in a lymphatic produce no visible reaction. It is only when the lymphatic has become distended by the growth within it that round-celled infiltration and other signs of inflammatory reaction are manifested around it.

Distribution of the Secondary Deposits.

If cancer is distributed by the blood stream, the cancer emboli should lodge by choice in the terminal arteries, especially at the extremities of the limbs, and should affect with equal frequency the side on which the growth originates and the opposite side of the body. Invasion of the lungs, in which the emboli must lodge before they can reach the systemic circulation, should be more frequent than that of the other viscera. A general outburst of metastases at widely different points all over the body should follow the infection of the blood stream.

This is not the picture of cancerous dissemination. The process clinically begins by the embolic invasion of the nearest set of lymphatic glands—clear evidence that the disease is using the lymphatic channels. Next, secondary nodules appear—always in the immediate neighbourhood of the primary growth. In the subcutaneous tissue the nodules spread in a centrifugal manner away from the primary growth, involving a gradually increasing circular area centred upon it. In exceptional cases this circular area may extend up to the scalp, down below the

groins, and as far as the middle of the humerus, but the forearms and legs are almost invariably free, though they are election sites for non-cancerous embolism. So too, the bones below the elbow and the knee are only very rarely the sites of secondary deposits. The proximal ends of the humerus and femur are invaded more frequently than the distal ends. Piney has attempted, though unconvincingly, to explain this difference as due to the persistence of red marrow in the proximal, but not in the distal ends of these bones. Willis stresses the importance of local differences of " soil " for the incipient metastases as determining metastatic distribution.

Transcœlomic Implantation.

The slow spread of permeation ultimately carries cancer-cells either to the subpleural or the subperitoneal lymphatic plexus. Shortly afterwards, by erosion or rupture of the permeated subserous lymphatics, cancer-cells escape into the serous cavity. From this moment events march with rapidity to a fatal end. The cancer-cells distribute themselves widely through the serous cavity under the influence of gravity and of visceral movement. They attack the viscera which are in relation to the serous membrane, and soon visceral deposits manifest themselves. Prognosis, hitherto obscure, now becomes easy—death within a year.

In rarer cases, invasion of the cranial cavity either by permeation upwards along the main deep cervical chain of lymphatics, or by blood embolism, may terminate the case.

Bone Deposits in Cancer.

In 1906 an examination of the bone deposits in 329 cases of breast cancer led me to question the doctrine that such deposits arise from blood dissemination. It appeared that in general the liability of a bone to cancerous deposit increases with its proximity to the site of the primary growth, and that the bones distal to the knee and elbow escape invasion except in the rarest instances.

The point of invasion of the femur was found to be the base of the great trochanter, that of invasion of the humerus the deltoid insertion. These are subcutaneous areas where the bone is in close contact with the fascial plexus, which, as we have seen, is the main highway of parietal permeation. It appeared highly probable, therefore, that the centrifugal spread of permeation through the fascial plexus was the agency which carried infection to these bones. The conclusion was supported by the observation that out of eight cases in which only one femur was affected by growth, the disease was on the same side as the primary breast growth in six cases. Such a preference for the side of the primary

growth, when considered in connection with the almost universal escape of the distal bones of the limbs, seemed quite inconsistent with such a process as blood embolism which would affect impartially both sides of the body, and would for choice attack the distal portions of the limbs, where non-cancerous emboli often lodge. Spontaneous fracture of the humerus, it is true, seemed to be more frequent on the contralateral side, but this might be accounted for, as a rule, by the surgical clearance of the axilla on the side of the growth.

It was not difficult to apply the permeation theory to other bone deposits, and deposits in the cranial bones can be explained by the extension upwards along the lymphatic vessels of the deep cervical chain. Similarly, permeation along the lymphatic vessels of the intercostal spaces to the glands which lie upon the necks of the ribs will account for deposits in the thoracic vertebræ, and particularly for the special incidence of such deposits upon the upper thoracic vertebræ (third to sixth) which Carnett has recently demonstrated. The corresponding intercostal spaces are in specially close relation to the breast.

Carnett and Howell ("Bone Metastases in Cancer of the Breast," *Ann. Surg.*, June 1930, 811), in 204 advanced cases of breast cancer submitted to X-ray examination during life, found bone deposits in 49·5 per cent. Secondaries in bone are a late development, usually occurring two years or more after the onset of symptoms. Thus they are not seen in the more rapid type of carcinoma. The arrest of local manifestations of disease by efficient operation has of late years increased the number of those who survive to die of bone deposits.

In early cases of bone invasion, Carnett finds that, apart from direct extension to ribs underlying the breast lesion, the order of frequency is: (1) the homolateral shoulder-girdle (head of humerus and glenoid region of the scapula); (2) the third to the sixth thoracic vertebræ; and (3) the upper lumbar vertebræ.

In 54 cases of metastasis to the shoulder-girdle the deposits were bilateral in 24, homolateral in 23, and contralateral in only 7. Studies of the humerus revealed a gradually progressive extension of the disease downwards in the bone. In only 6 cases were deposits present below the elbow, usually first in the head of the radius. Metastasis then spreads downwards in the radius and ulna and may involve practically the whole length of these bones. Deposits may appear in the bones of the hand if all three long bones of the arm are extensively involved, but not otherwise. A similar downward progress of the disease is traced in the lower extremity, where the deposits begin in the femoral head and

the acetabulum. In only two cases of their series of 101 cases did Carnett find it necessary to attribute the metastases to blood embolism.

Carnett was the first to point out the importance of permeation along the deeper lymphatic chains, such as those within the abdomen, or along the intercostal spaces, for the genesis of bone deposits. He draws attention to the great frequency of cancerous invasion of the aortic and iliac glands, often in the absence of any enlargement of the inguinal glands. Around such glands he often demonstrated permeated lymphatics. Secondary permeation around the glands leads to the invasion of the lumbar vertebræ, lower ribs and pelvis.

Piney has attempted to account for the peculiar distribution of metastatic tumours in bones in another way. He states that red marrow disappears from most of the bones in adult life, but that it persists in the upper end of the femur and the upper end of the humerus,

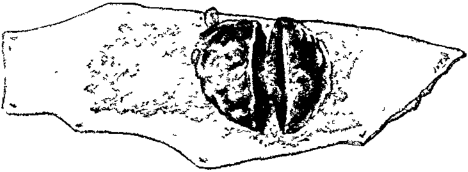

Fig. 2280.—A melanotic sarcoma of the skin pedunculated and partly bisected The skin around shows a brown discolouration due to the lymphatic spread of the growth.

(*Museum, Middlesex Hospital.*)

and forms a favourable nidus for carcinoma cells. Willis elaborates the hypothesis by assuming that, if carcinoma destroys the red marrow in the proximal end of the bones, a compensatory development of red marrow may occur lower in the bone, so that the disease is able to spread centrifugally down it. These explanations do not carry conviction. (Piney, *Brit. Journ. Surg.*, 1922, X, 235.)

At present the weight of evidence seems to point to the conclusion that carcinoma is usually carried to bones by lymphatic channels, but occasionally by the blood stream. Controversy will continue until further evidence is produced.

Dissemination of Melanotic Sarcoma.

The black pigment of melanotic sarcoma (and that the growth is a sarcoma, not a carcinoma, was many years ago established by Ribbert) enables its spread to be traced with accuracy and with relative ease. The available evidence shows that the earlier stages of dissemination are brought about by lymphatic permeation and lymphatic embolism.

In the later stages, blood dissemination is superimposed upon lymphatic dissemination, but fortunately not at such an early date that the success of timely operative intervention is excluded. The average duration of melanotic sarcoma from the time of onset to death is three years, and *the disease is not so intensively malignant as it is reputed to be.* The usual operative treatment of the disease, even at the present day, is *irrational and inadequate, and accordingly unsuccessful.*

The progress of melanotic sarcoma is best followed by taking a secondary focus of the disease in a superficial lymphatic gland, and by examining a long radial strip of the tissues around the infected gland. Around the gland, secondary cutaneous nodules appear and spread away from it in a centrifugal manner. It may be inferred that a process of local centrifugal spread, independent of the "set" of the lymph current, takes place round the gland as a focus. Microscopic examination shows that permeation of the lymphatics is the primary process concerned, and that it occurs first and principally in the plane of the fascial lymphatic plexus. Permeation is found in the plane of the deep fascia beyond the region of visible nodules, and where neither the muscle, the subcutaneous fat nor the skin is invaded. In the end of the strip near to the gland, upstream permeation of the cutaneous and muscular tributaries of the fascial plexus produces nodules in the skin and muscle. Here, too, it is seen that, owing to the concomitance of lymphatics and blood-vessels, rupture of a permeated lymphatic leads to the enveloping of the associated artery and vein in a sheath of cells, which infiltrate the walls of the blood-vessels and finally enter the lumen, at first, of the thin-walled veins and, later, of the arteries. It is at this point that lymphatic dissemination becomes of secondary importance. The interested reader will find more detail in my lectures on "The Pathology of Melanotic Growths" (*Lancet*, April 6th and 13th, 1907).

Embolic distribution of the growth by the blood leads to widespread visceral metastases. Melanuria, always a late symptom, may occur from embolism of the renal glomeruli.

But even at the time of death it is the rule that the secondary deposits are much more abundant on the side of the body on which the tumour originated. This fact shows that the earlier stages of dissemination are due to local (lymphatic) spread. In rare cases after death practically all the lymph glands of the chest and abdomen may be enlarged by secondary deposits while the viscera are almost free of nodules which could be ascribed to blood embolism. Probably, therefore, as in carcinoma, the blood may exert a destructive effect upon the cells of melanotic sarcoma.

Blood Dissemination a Late Event.

Though blood dissemination is almost invariable in melanotic sarcoma it is fortunately late. This is shown by microscopic evidence, by the long average duration of the disease, and by the occasional success of rational operative treatment, even in recurrent cases with heavily infected glands. A patient with a recurrent melanotic sarcoma of the upper arm, operated upon by a "monobloc" operation when the axillary glands were already much enlarged, died eighteen years later without recurrence. Figure 2278 shows that the "monobloc" operation is possible even in such a difficult situation as the face.

CHAPTER V

Elephantiasis

by

Philip Manson-Bahr

Elephantiasis is a condition in which the lymphatic tissues mostly are concerned, and it may be defined as a progressive histopathological state characterised by fibrosis and hyperplasia of the dermis and subdermal tissues.

Since early times it has been noted that elephantiasis is more common in the tropics than in the temperate countries, and though the cause of the tropical form is now known to be the filaria (*Wüchereria bancrofti*), yet elephantiasis with indistinguishable clinical features is found all over the world.

It is necessary at the outset to distinguish elephantiasis from lymphatic œdema, which is a condition of solid œdema without hypertrophy.

The term *Elephantiasis nostras* has been generally applied to the non-parasitic form in order to distinguish it from filarial elephantiasis (formerly known as *E. arabum*).

CLASSIFICATION

In the rather incomplete state of our present knowledge it is difficult to find an entirely satisfactory classification. The following, however, is based upon the classification adopted by Bertwistle and Gregg (1928):

1. *Congenital.* A condition first described by Milroy and Meige in which there appears to be an hereditary maldevelopment of the lymphatic vessels and tissues which manifests itself as œdema. Apparently two types can be distinguished, simple and familial.

Simple congenital lymphœdema affects single individuals in a family; *familial* congenital lymphœdema affects a sufficient number of blood relatives to suggest an hereditary disposition. This condition is sometimes described in medical text-books as "hereditary trophœdema."

2. *Traumatic.* Under this heading those cases of elephantiasis are included which result from extensive destruction of glands, and which

are usually associated with cicatricial contraction of the connective tissues. This has been recorded as the result of removal of tuberculous inguinal glands, and as the result of infection with the virus of *lymphogranuloma inguinale* (climatic bubo).

It is also recorded that in former years excision of enlarged inguinal glands was practised on recruits for the army in order to enable them to pass the medical tests, and in some cases elephantiasis of the legs or genitals resulted.

3. *Infective.* A number of micro-organisms and parasites which affect the lymphatic glands and vessels are included under this heading:

(*a*) *Filarial Elephantiasis. Wuchereria bancrofti* (*Filaria bancrofti*) is by far the most frequent and is found in most tropical countries, being especially abundant in India, China and Polynesia. In this condition the adult worms of both sexes live in the lymphatic system, and the embryos emitted by the females pass via the lymphatic vessels and glands into the blood stream.

Patients infected with this filaria are especially liable to superimposed *septic infections*, and these may play a part in the ultimate blockage of lymphatic tissues. It is now, however, generally held that the effects of the filaria alone are sufficient to cause extensive lymph stasis.

Similar elephantoid conditions are sometimes caused by a filaria worm of another genus —*Onchocerca volvulus*.

(*b*) *Tuberculous.* Tuberculous infection of lymphatic glands and tissues is well known, and in chronic ulceration of the groin glands in lupus of the skin with concomitant infection of the lymphatic vessels, an elephantoid condition of the limb may supervene as in the case described by J. A. White (1924).

(*c*) *Spirochætal.* In long-standing syphilitic gummatous ulceration of the thigh, and in the analogous case of yaws associated with fibrosis and cicatricial contractures, lymph stasis and elephantiasis may supervene.

(*d*) *Leprotic.* Elephantoid thickening of the skin and subcutaneous tissues frequently supervenes in chronic leprosy, and is undoubtedly due to direct infection of the lymphatic vessels with the leprosy bacillus.

(*e*) *Granulomatous.* In the condition known as *Granuloma venereum*, which is a particularly chronic ulcerating disease affecting the tissues of the groin, the main lymphatic vessels may be involved and lymph stasis may supervene. The same process may occur in *lymphogranuloma inguinale* (or climatic bubo), which is caused by a virus with special affinity for the lymphatic system.

(*f*) *Malignant.* It is well known that lymphatic spread of carcinoma, especially of the more chronic and slow-growing varieties, may rarely cause lymphatic hyperplasia.

(*g*) *Bacterial.* Streptococcal and staphylococcal infection of the lymphatics following upon some septic abrasion of the foot or leg is undoubtedly a *not-infrequent cause of elephantiasis of the* lower limbs. The elephantoid state is preceded by frequent and violent attacks of septic lymphangitis, in which the streptococcus can usually be demonstrated. This condition may sometimes supervene upon surgical operations upon the legs.

(*h*) *Toxic.* Apparently, rarely, chronic absorption via the lymphatics of some irritating toxin may cause such destruction of lymphatic tissue as to produce an elephantoid condition indistinguishable from filarial elephantiasis. The writer in 1920 described a case of elephantiasis of the scrotum in a man of sixty years of age who for thirty years had treated a large patch of psoriasis on the left buttock with daily inunctions of chrysarobin. The urine contained a cloud of albumen and renal cells.

GENERAL CONSIDERATIONS ON LYMPH STASIS

Views upon the mechanism of production of lymph stasis and lymphatic hyperplasia have been considerably altered by recent work. It was formerly considered necessary that, in order to obtain complete lymph stasis, blockage of one or more of the main venous trunks must be produced, and it was thought that the mechanism of lymphœdema in man differed from that in experimental animals. Drinker and Field (1934) have, however, brought about true elephantiasis in the legs of dogs by centripetal injection of irritants into the lymphatic trunks. At first they produced this effect by injecting 2–4 cc. of a watery suspension of crystalline silica into a lymphatic, followed by the same quantity of a 2·5 per cent watery solution of quinine hydrochloride. The silica causes the proliferation of the endothelium of the lymphatic vessel, whilst the quinine acts as the sclerosing agent.

Furthermore, these workers demonstrated that the limbs of the experimental animals showed enormous dilatation of the tissue spaces with a fluid rich in proteins, the albumen : globulin ratio being the same as that of the plasma.

After the appearance of the elephantiasis, the tissues are attacked by an acute generalised superficial inflammation due to a hæmolytic streptococcus. Recently, similar results of complete lymph blockage have been obtained by the gradual infiltration of indian ink. It is

therefore seen that there is striking analogy between the experimental elephantiasis produced in dogs and the natural disease as it appears in man.

PHYSIOLOGICAL CONSIDERATIONS

Lymph is usually regarded as a transudate from the veins—indeed, lymphatic vessels themselves are in reality modified veins in which the endothelium, when once formed, retains specific characters.

The work of Drinker and his colleagues goes to show that vascular endothelium permits salts, electrolytes and proteins to pass through it into the tissue spaces. These latter return to the blood-plasma through the vascular endothelium, whilst the proteins are absorbed into the lymph stream by the lymphatic endothelium.

The thesis formulated by Starling in 1896 still holds good, namely, that the balance between the osmotic pressure of the plasma proteins and the capillary blood-pressure is the underlying mechanism regulating the movement of water across the capillary wall. That there is an intimate relationship between venous pressure and lymph production is seen when, after pressure is raised in the lobular capillaries of the liver, an immediate outpouring of highly proteinised lymph from the thoracic duct occurs.

It has also been recorded in some cases of slowly developing cirrhosis of the liver, that an extensive varicosity of the lymphatics of the abdominal wall and solid lymphœdema of both legs may ensue.

It appears that, in order to produce the true elephantoid state, there must be a transudation of lymph and that this transuded lymph must contain an excess of protein, such as occurs when a lymphous exudate collects as the result of the inflammation, and this, in turn, acts as a cell stimulant so as to produce lymphatic hypertrophy and hyperplasia, for it forms an ideal culture medium for proliferating cells.

Superficial lymphatic capillaries are specially abundant and contain actively circulating lymph which continues to flow, even when the limb is at rest, and it has further been ascertained that the flow from the forearm to the axilla is very rapid, and that material introduced into the forearm reaches the axillary glands in less than ten minutes. Furthermore, Woollard and Gray have shown that material injected into the great toe may be present in the large lymphatic trunks above the ankle in two minutes and that it travels via the lymphatic capillaries.

The lymph stream has a well-defined series of directions of flow from different areas of skin with sharp lines of demarcation between them. The discovery of these delimited areas shows that the former

conception of a generalised lymphatic anastomosis is incorrect, and this fact must therefore be taken into account in planning surgical operative measures.

The superficial lymphatics are the most important and extensive part of the lymphatic system, so that the tissue changes following lymphatic obstruction are more pronounced in the *integument and* subcutaneous tissues, and little hypertrophy occurs in the deeper tissues. *Woollard and Gray*[1] *have shown that the lymphatic supply* of the skin is particularly rich, and that the vessels lie mainly in the superficial part of the dermis placed at a slightly deeper plane than the arterioles which give off loops to the dermal papillæ. There is a wide-meshed plexus of fairly straight vessels, each of great length compared to their lumen, lying parallel to the skin surface, and these vessels contain no valves.

In the deeper layers the lymphatics form a series of collecting radicles rather than a true plexus, but they are joined to the superficial plexus by more or less vertically placed vessels. The collecting trunks possess valves situated about 1 mm. apart.

The lymphatics of the subcutaneous tissue are large drainage trunks which have no association with the larger subcutaneous veins. There is therefore a clear separation of the superficial, or external, lymphatic system from the deep, or internal, system with the deep fascia intervening as a boundary between them. *The deep fascia is devoid of lymphatics.*

THE PATHOLOGY OF CONGENITAL LYMPHŒDEMA

Comparatively little work has been done on the pathology of this obscure disease, and this for the most part on tissues removed at operation. On microscopic examination the skin and deep fascia appear normal; but the distance between the two is greater than in *normal tissues. The outstanding appearance is that of a sponge.* The fibrous tissue contains numerous widely dilated lymph spaces which are seen in the septa and corium as well. The microscopic appearance of these tissues is characteristic. The predominant feature is the replacement of adipose tissue by enlarged lymphatic spaces surrounded by loosely woven connective tissue.

Congenital lymphœdema is therefore characterised by the replacement of the normal subcutaneous fat by widely dilated lymph spaces and by fibrous tissue.

Possibly the increased surface area occupied by lymphatic vessels

[1] Woollard (H. H.) and Gray (J. H.). The author acknowledges his indebtedness for their permission to refer to their hitherto unpublished researches.

creates a state tending to produce lymph stasis, which results in fibrosis, as lymph constitutes such a good culture medium for fibroblasts. This lymphangiectasis may therefore be viewed as a developmental anomaly.

THE PATHOLOGY OF FILARIAL ELEPHANTIASIS

A consideration of the mechanism of the production of tropical elephantiasis entails a study of the natural history of *Wüchereria bancrofti*. These parasites are long hair-like transparent nematodes possessing a chitinous cuticle (fig. 2281). The sexes are found generally coiled together in the lymphatic vessels and glands; when they inhabit the latter, as O'Connor has shown, the parasites are found in the afferent lymphatic vessels and in the cortical sinuses.

Fig. 2281.—W. BANCROFTI (NATURAL SIZE). A. MALE. B. FEMALE. (*Manson's "Tropical Diseases."*)

The *male* is 40 mm. in length by 0·1 mm. in breadth, and is distinguished from the female by the small size and the corkscrew-like tail. The *female* measures 65–100 mm. in length by 0·28 mm. in breadth. The ova in the upper portion of the uterus contain well-formed embryos enclosed in a membrane which subsequently becomes the sheath of the embryonic filaria (or microfilaria) as it appears in the blood stream.

These embryos (microfilariæ) (fig. 2282) emitted by the viviparous female filaria pass with ease and without injury through the lymphatics and lymphatic glands (Drinker, Augustine and Leigh, 1935).

Eventually they gain the blood stream and appear in the blood. Whether they do so via the thoracic duct, as has been so frequently stated, is a moot point, as it has been shown by Augustine and Drinker (1935) that microfilariæ can readily leave the circulation and enter lymphatic vessels by their own volition.

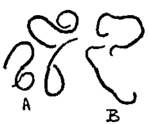

Fig. 2282.—DISTINGUISHING FEATURES OF MICROFILARIA BANCROFTI AND MICROFILARIA LOA, IN STAINED SPECIMENS. ATTITUDES (A) OF MICROFILARIA BANCROFTI, (B) OF MICROFILARIA LOA. (*Manson's "Tropical Diseases."*)

The adult filariae during life appear to cause but little destruction to the tissues they inhabit, beyond causing local fibrotic thickening of the vessel wall, but where the tissues have been previously damaged, the migration of the embryos emitted by the parent filaria becomes impeded and the microfilariæ become imprisoned by the proliferation of the lymphatic endothelium, as the writer originally demonstrated, and as has been exemplified by O'Connor's recent work.

When the mature worm dies, it becomes cretified and continues to act as a tissue irritant and lies, like a mummy, in the lymphatic glands and vessels surrounded by a sarcophagus of inflammatory tissue (fig. 2283).

The writer originally showed in 1912, a fact abundantly confirmed by O'Connor (1931), that by repeated infection with adult filariæ a condition of hyperfilariation is produced in which all the main lymph channels (say, of the groin) are blocked by cretified filariæ and the lymphatic fibrosis they bring about, whilst the function of the

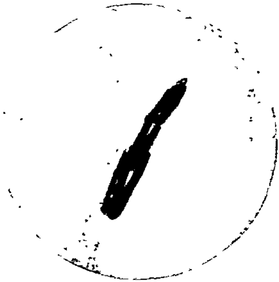

Fig. 2283.—Microphotograph.
(P. Manson-Bahr)

lymphatic glands is destroyed by fibrosis and giant-cell proliferation, and thus complete occlusion of the lymph channels is brought about.

Thus the pathology of lymph hyperplasia in filarial elephantiasis may be satisfactorily explained on the known pathology of filarial disease. That it is a central blockage and that it acts essentially in much the same manner as in hereditary lymphœdema, there can hardly be any reasonable doubt (O'Connor, Golden, Ross and Auchincloss).

In the pathologically-produced elephantoid tissue the cretified remains of dead adult filariæ can be demonstrated by X-ray examination (Golden and Auchincloss). Furthermore, O'Connor has shown that the periodic attacks of inflammation in tropical elephantiasis or lymphangitis arise from "focal spots" which are foci of a low form of suppuration containing the remains of dead filariæ in elephantoid tissue.

There is one aspect which has been the subject of much speculation, namely, the frequent absence of the characteristic microfilariæ in the

blood of victims of elephantiasis. The answer surely is that the existence of such a large area of lymph blockage precludes the entry into the blood stream of microfilariæ from that lymph area. Consequently there is a lesser likelihood of the parent filariæ procuring an unobstructed passage into the blood for their embryonic young.

THE CLINICAL FEATURES OF FILARIAL ELEPHANTIASIS

Filarial elephantiasis, when fully developed, is so characteristic as not to warrant any particular description. It usually occurs in an

Fig 2284.—ELEPHANTIASIS OF THE SCROTUM, SHOWING THE SCAR OF A HEALED ABSCESS. (*Photograph by P. Manson-Bahr.*)

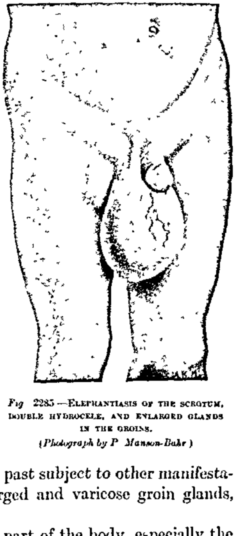

Fig 2285.—ELEPHANTIASIS OF THE SCROTUM, DOUBLE HYDROCELE, AND ENLARGED GLANDS IN THE GROINS. (*Photograph by P. Manson-Bahr.*)

individual who has been for some time past subject to other manifestations of filarial disease, such as enlarged and varicose groin glands, hydrocele, chyluria, etc.

This elephantiasis may attack any part of the body, especially the legs, scrotum (figs. 2284 and 2285) and penis in the male, the vulva in the female, the arms (fig. 2286 and 2287) and the mammæ (fig. 2288).

More rarely, localised and pedunculated forms of elephantiasis have been reported on the scalp, face, buttocks, thighs and other parts of the body.

The subjoined table is made from statistics of 4712 cases collected by Stephens and Yorke:

RELATIVE FREQUENCY OF PARTS ATTACKED.

Legs.	Scrotum.	Arms.	Legs and Scrotum.	Legs and Arms.	Legs, Arms and Scrotum.	Breasts.
57%	35%	0·9%	0·9%	3·5%	0·8%	0·1%

It is to be noted that involvement of more than one part such as the legs and scrotum is less frequent, but the parts affected vary much in different countries. In the Pacific form of filariasis (the non-periodic *W. bancrofti*) the arms are more frequently attacked than in other parts

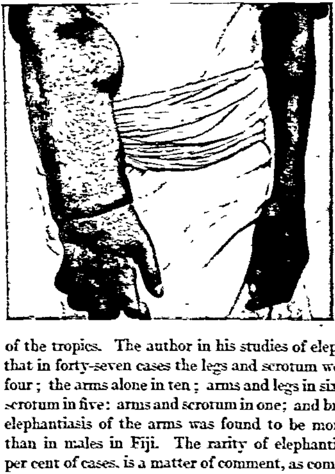

Fig. [illegible].—ELEPHANTIASIS OF RIGHT ARM IN A FIJIAN. (*Photograph by P. Manson-Bahr.*)

of the tropics. The author in his studies of elephantiasis in Fiji noted that in forty-seven cases the legs and scrotum were affected in twenty-four; the arms alone in ten; arms and legs in six; both arms, legs and scrotum in five; arms and scrotum in one; and breast in one. Curiously, elephantiasis of the arms was found to be more common in females than in males in Fiji. The rarity of elephantiasis of the vulva, 0·8 per cent of cases, is a matter of comment, as compared to the frequency of elephantiasis scroti in the male. This is possibly explained partially by natural reticence on the part of the sufferers to exhibit these parts. It is possible, too, that the rather more abundant lymphatic supply of these parts in the female militates against complete blockage. Enlargement of the lymphatic glands draining the area is an almost invariable accompaniment of elephantiasis. In the case of the leg it is the inguinal

glands, and in the case of the forearm the epitrochlear. In 1912 the author showed that enlarged epitrochlear glands, often of considerable size and very common amongst the Fijians, form prominent and noticeable tumours and are usually the precursors of elephantiasis of the forearm. When excised, numerous adult filariæ can usually de demon-

Fig. 2287.—Elephantiasis of both arms and left leg in a Samoan

(*Photograph by Dr Davies, Samoa*)

strated in the sinuses of the gland. These baggy lymphatic swellings containing enlarged glands are usually observed above the internal condyles in elephantiasis of the upper extremities. This has been confirmed by Professor P. A. Buxton in Samoa.

CLINICAL PECULIARITIES

The onset of true elephantiasis may be painless and gradual, accompanied by a gradually developing œdema. On the other hand, the

actual commencement usually dates from the first attack of *lymphangitis*. This is usually sudden, and manifests itself by an erysipeloid attack accompanied by a rigor, pyrexia, vomiting and body pains. The attacks recur at regular intervals, and after each the lymphatic œdema becomes more pronounced and is consequently of longer duration.

The process of the disease varies considerably in various cases.

During the *first* stage there is uniform swelling and thickening of the part. The overlying skin is smooth, pale, and cool.

During the *second* stage the skin becomes coarser and more thickened and acquires an uneven ridged appearance, and this usually coincides with some hypertrophy of the adjacent muscles.

In the *third*, or fully developed stage, the skin and subcutaneous tissues become greatly hypertrophied and, in the case of the lower limb, there are considerable folds separated by deep sulci, occurring mostly at the folds, whilst in the case of the scrotum there is a diffuse ruggedness. The skin may become studded with bosses, numerous wart-like projections (*E. verrucosa*), or fissures, whilst ulcers or abscesses may form. When the ankle and foot are swollen and the toes unaffected, the peculiar "tortoise foot" appearance is seen. At this stage, too, the muscles may show signs of pressure atrophy, and some bone distortion may be observed. When the feet are affected by these verrucosities the condition known as "mossy foot" is produced.

As the disease progresses, the intervals between the attacks of lymphangitis are prolonged until they cease altogether.

The blood supply to the parts affected by elephantiasis is very great, and the veins especially become enormously enlarged.

Elephantoid tissue does not pit readily, and firm prolonged pressure is required to cause an indentation. It has been pointed out by Gregg and Bertwistle that this observation has a practical application in the use of the tourniquet applied over elephantoid tissue before operation. When first applied, the tourniquet may be efficient, and later on indentation occurs, sufficient to permit arterial flow, but tight enough to prevent venous return and so cause profuse hæmorrhage.

TREATMENT

General measures. The subject of treatment of elephantiasis is a prolonged affair and cannot be readily dismissed. These measures may be discussed under the following headings:

(1) *Focal sepsis.* In the successful treatment of elephantiasis, especially as a preventative measure, attention must be directed to any source

of focal sepsis. The septic foci may be, and often are, septic teeth, whilst Sistrunk reports that in two of his cases the tonsils were grossly infected. Though teeth and tonsils probably form the chief source of infection in non-tropical elephantiasis (*elephantiasis nostras*), chronic appendicitis and pelvic or urinary infection may also be held responsible.

(2) *Vaccines and protein shock.* As it has been pointed out by numerous workers on this subject, the author by his work in Fiji, by F. G. Rose in British Guiana, and especially by the Filariasis Commission to British Guiana in 1924, septic infections are a very frequent accompaniment of filarial diseases, as they also are in *elephantiasis nostras*, and prophylactic injection with mixed streptococcal and staphylococcal vaccine is advisable, especially preparatory to operation. A polyvalent vaccine (killed cultures) composed of ten million streptococci with ten million staphylococci (*S. pyogenes aureus*) given at weekly intervals is a rational method. In British Guiana these therapeutics have been utilised, apparently with some success, as a method of preventing or warding off further attacks of lymphangitis or elephantoid fever.

Protein shock therapy, given on empirical grounds, using intravenous injections of killed typhoid-paratyphoid cultures (T.A.B. vaccine) in doses of fifty and a hundred million organisms, which causes a considerable systemic reaction, has been found to exert some influence upon early elephantoid conditions, and to cause a temporary reduction of the swelling. This method is always worth trying in the pre-operative treatment of the disease. If the patient is in an enfeebled physical condition, this method is contra-indicated.

(3) *General health.* It is most important that the general health should be attended to, and any other concomitant infections should be dealt with. In native races these are commonly malaria and almost universally an ankylostome infection. This helminth, as well as other worms such as ascaris, should be removed by the combined carbon tetrachloride and oil of chenopodium treatment.

(4) *Local measures.* In the earlier stages of elephantiasis of the leg, the patient should be encouraged to persist with bandaging with elastic bandages, massage, and elevating the limb whenever possible, and later some control may be obtained by tight elastic bandaging or by stockings which should be made to fit accurately and should be constructed of some porous or easily washed substance, such as stockinette. A perfectly fitting stocking should embrace the dorsum of the foot, should accurately fit the leg, and reach above the knee. Usually, difficulty is experienced with the upper margin, which extends to the thigh and is apt to constrict at this point. To obviate the pressure of tight-fitting

stockings, and to accommodate the fluctuations in the size of the limb, the stockings may be made to lace up at the sides (fig. 2289).

Finally, it is essential that the affected limb should be elevated and supported by *crêpe* bandages, and massage applied daily. The latter should be both deep and vigorous.

THE OPERATIVE TREATMENT OF ELEPHANTIASIS

Sampson Handley in 1908 first realised the importance of re-establishing the lymph flow, and this he attempted to do by the subcutaneous insertion of silk threads. Later, Lexer modified this method by substituting strips of fascia for the silk threads, but the results were generally unfavourable. Walther further modified the method by burying a rubber tube between the deep fascia and the layer of muscle. The lower end of the tube was left protruding through the deep fascia into œdematous tissue and the upper end was similarly placed in normal tissue. Next Lanz tried to increase the poor anastomosis between the deep and superficial lymphatic systems of the lower limb by inserting a strip of subcutaneous tissue between the intermuscular septum and suturing it into holes drilled into the bone.

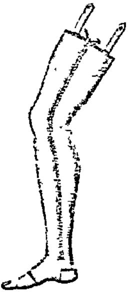

Fig. 2289.—Laced form of elastic stocking, with suspenders, adjustable so as to avoid pinching. (*Hospital and General Contracts Co.*)

Kondoléon's operation, which has been much practised, aims at removing strips of œdematous skin, subcutaneous tissue and deep fascia, two inches wide, medially and laterally from the entire leg. This method has frequently given good results. The success of this operation may be ascribed to the removal of the deep fascia which has been shown by Woollard and Gray to form a barrier to lymphatic anastomosis, and also to their showing that blocked lymphatic capillaries, whilst incapable of forming functioning anastomosis with normal lymphatic capillaries, whose drainage is normal, *can* form such an anastomosis with normal lymphatic capillaries when both have been incised by surgical means. The anastomotic union apparently only occurs amongst the minute lymphatic capillaries.

Since Kondoléon first devised the operation, modifications have been made, especially by Sistrunk who carries it out in two stages.

One side of the extremity is operated upon throughout its entire length at the first stage, and two to three weeks later, the other side is dealt with. At the first operation an elliptical incision narrowing at the

knee is made from the iliac crest to the ankle on the lateral surface, and at the second operation from the groin to the ankle on the medial surface, a sufficiently large portion of skin being removed to reduce the size of the limb to normal.

The margins of the skin are then dissected back for a distance of 6 cms. or more on each side, and the œdematous tissue incised downwards through the deep fascia. The skin, œdematous tissue and deep fascia down to the muscle are removed in one piece.

This allows a broad communication between the superficial tissue and underlying muscles. The skin is closed without drainage and close

fitting bandages are applied. Immediately following operation, normal saline solution is given per rectum and also subcutaneously.

Sistrunk's post-operative treatment consists in wearing an elastic stocking or bandage for an indefinite period.

Ghormley and Overton have reported on 55 patients operated upon since 1923, of which 50 per cent showed considerable improvement and 11 per cent complete relief. All cases reported on were of the non-filarial form of elephantiasis.

A. L. Gregg reported a successful treatment of an extreme case of elephantiasis of both legs (figs. 2290 and 2291) by successive operations in seven stages, in which practically all the elephantoid tissue on

rind of skin which is thickest towards the lowest and most dependent part, and beneath it a mass of blubbery œdematous tissue in which testes, cords and penis are embedded. The tumour is therefore more or less pyriform in shape (fig. 2293).

Great care must be taken in identifying and separating out the testes and cords. The arteries which supply these enormous growths are of considerable size, and the veins are also very large and bleed freely.

It is necessary that care should be taken in the pre-operative stage, and that the patient should keep to his bed for a week beforehand.

The patient should be placed in the lithotomy position on a horizontal table. The scrotum should be drawn down as far as possible and elastic webbing applied over the mass to expel the blood.

A vertical incision is made commencing in the middle of the symphysis pubis and extending as far as the aperture leading to the penis. The penis is expressed and the penal artery ligatured. A sound is passed to prevent subsequent injury to the urethra. The vertical incision is continued round the scrotum right round to the perineum, and the scrotum divided into two halves.

The testes and cords are now separated from the blubbery mass, the hypertrophied gubernacula being divided, surrounded with gauze and placed on one side. At the base of each half of the scrotum clamps are fixed, care being taken that they are well on to the proximal side of all diseased tissue.

Each half of the scrotum is then cut away distal to the clamps and through healthy tissue. All visible blood-vessels should be secured and tied and the clamps gradually loosened. The skin of the upper and inner aspects of the thigh is undermined and brought together over the testes.

Thiersch skin grafts may be applied to the penis and good cosmetic results are obtained.

fitting bandages are applied. Immediately following operation, normal saline solution is given per rectum and also subcutaneously.

Sistrunk's post-operative treatment consists in wearing an elastic stocking or bandage for an indefinite period.

Ghormley and Overton have reported on 55 patients operated upon since 1923, of which 50 per cent showed considerable improvement and 11 per cent complete relief. All cases reported on were of the non-filarial form of elephantiasis.

A. L. Gregg reported a successful treatment of an extreme case of elephantiasis of both legs (figs. 2290 and 2291) by successive operations in seven stages, in which practically all the elephantoid tissue on

both legs and labia was removed. The operation consisted of removal from below upwards of as much elephantoid tissue as possible by means of elliptical incisions and undermining, thus removing large masses of blubbery tissue, including underlying portions of deep fascia. The incisions were so planned that the skin edges could best be brought together.

Auchincloss' operation is a modification of Kondoléon's technique and is intended to remove these tender "focal spots" in which the calcified filaria worms are situated in filarial elephantiasis. It consists of two incisions marking out a vertical strip of skin. From its ends V-shaped incisions are made, diverging upwards at the upper end and downwards at the lower. A great amount of skin is undermined with considerable care at a level deep to the corium (fig. 2292).

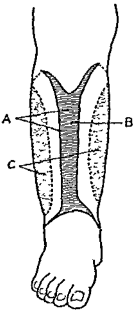

Fig 2292.—Scheme for Auchincloss' operation for elephantiasis.

A. Incisions. B Skin excised. C Shows extent of subcutaneous tissue and deep fascial excision posteriorly This excision is planned to remove maximum number of calcified areas and "focal spots."

(*Reproduced from the "Porto Rico Journal of Public Health and Tropical Medicine."*)

Selection of cases. The selection of cases for operative treatment is regarded as a most important factor. Recent attacks of cellulitis should not constitute a contra-indication. The severe cases give the best results and the improvement in the milder cases tends to be disappointing.

Gillies' and Fraser's Operation. This is a plastic operation which has recently been introduced and is still on trial. The operation has been reported upon at length by A. H. McIndoe. The operative technique has been planned upon the expectation that the existing lymphatics of the lower limb will anastomose with another set from the arm, if the two are brought together in surgical juxtaposition. This procedure rests upon the experimental work of Woollard and Gray who have shown that such an anastomosis of lymphatic capillaries with normal lymph vessels will take place if brought into contact by surgical means, but will not do so if a fibrous barrier intervenes. The lymphatics of the forearm are brought by means of a "flap" close to the upper and outer aspects of the thigh, with the idea of transporting the stagnated lymph via the arm lymphatics into the general lymphatic system via the thoracic lymphatics, and with the idea of forming a bridge across the impermeable lymphatic barrier in the pelvis.

The operation has been carried out so far in four stages. Incisions seven inches long are made on the flexor aspect of the forearm corresponding to the area on the elephantoid leg. Cross incisions are made at the extremities to enable two small flaps to be turned outwards and inwards respectively, passing through the deep fascia.

A similar area is laid bare on the corresponding thigh. By bringing these flaps into contact the deep fascia of the thigh is approximated to the deep fascia of the forearm, and the flaps are sutured on each side like wings, and are left in position with the arm bound to the side for three weeks or more till the union is complete. Further operations are undertaken to undermine the remaining portions of the flaps which now extend from the centre of the thigh to the axilla.

In the final operation the flaps are severed, and interchange of arm, body and leg skin completed. Only a limited number of cases have so far been subjected to this operation, but it may be stated that it promises well for the future.

OPERATION FOR ELEPHANTIASIS OF THE SCROTUM

This is an eminently satisfactory operation and aims at the removal of a redundant mass of tissue, so that considerations of subsequent lymph drainage do not apply.

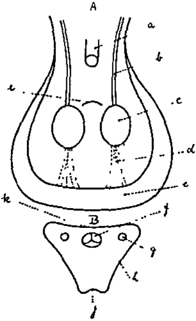

Fig 2293.—Diagram of anatomy of elephantiasis of scrotum

A. Diagram of scrotum.
- (*a*) Penis
- (*b*) Spermatic cords
- (*c*) Testes
- (*d*) Gubernacula testis
- (*e*) Hypertrophied skin.
- (*l*) Channel leading to penis.

B. Transverse section of neck of scrotum.
- (*f*) Penis.
- (*g*) Spermatic cords
- (*h*) Sides
- (*j*) Apex
- (*k*) Base.

The operation is commonly performed for the removal of scrotal tumours such as occur in most filaria-infested countries.

These tumours consist of two portions—the outer or hypertrophied

rind of skin which is thickest towards the lowest and most dependent part, and beneath it a mass of blubbery œdematous tissue in which testes, cords and penis are embedded. The tumour is therefore more or less pyriform in shape (fig. 2293).

Great care must be taken in identifying and separating out the testes and cords. The arteries which supply these enormous growths are of considerable size, and the veins are also very large and bleed freely.

It is necessary that care should be taken in the pre-operative stage, and that the patient should keep to his bed for a week beforehand.

The patient should be placed in the lithotomy position on a horizontal table. The scrotum should be drawn down as far as possible and elastic webbing applied over the mass to expel the blood.

A vertical incision is made commencing in the middle of the symphysis pubis and extending as far as the aperture leading to the penis. The penis is expressed and the penal artery ligatured. A sound is passed to prevent subsequent injury to the urethra. The vertical incision is continued round the scrotum right round to the perineum, and the scrotum divided into two halves.

The testes and cords are now separated from the blubbery mass, the hypertrophied gubernacula being divided, surrounded with gauze, and placed on one side. At the base of each half of the scrotum clamps are fixed, care being taken that they are well on to the proximal side of all diseased tissue.

Each half of the scrotum is then cut away distal to the clamps and through healthy tissue. All visible blood-vessels should be secured and tied and the clamps gradually loosened. The skin of the upper and inner aspects of the thigh is undermined and brought together over the testes.

Thiersch skin grafts may be applied to the penis and good cosmetic results are obtained.

CHAPTER VI

Hodgkin's Lymphogranuloma

by

Sir Humphry Rolleston, Bart.

Synonyms. Hodgkin's disease (Wilks), Lymphadenoma (Wunderlich), Lymphadenoma malignum, Lymphogranulomatosis, Malignant lymphoma. Anæmia lymphatica, Adénie (Trousseau).

Other synonyms are not entirely suitable; thus "pseudo-leukæmia," sometimes erroneously employed for this disease, was introduced by Cohnheim (1865) to describe quite a different pathological state, viz. the changes of leukæmia in the lymphatic glands without the corresponding blood picture. Virchow (1864) used the term lymphosarcoma which unfortunately caused confusion with sarcoma of a different and quite definite microscopical structure. The name probably most generally familiar in this country is lymphadenoma, but it has been used in other countries for enlargement of lymphatic glands quite different from, and of much less serious import than, Hodgkin's lymphogranuloma. Wilks, who in 1865 used the name "Hodgkin's disease," in 1889 drew a distinction between lymphadenoma and Hodgkin's disease. Turnbull has used the title Hodgkin's lymphogranuloma for more than a quarter of a century.

Definition. A progressive, usually chronic, condition with a characteristic hyperplasia of the hæmatopoietic tissues, which may extend to other structures and behave like a malignant growth (Hodgkin's sarcoma). It is probably due to an ultra-microscopic virus. Though it responds temporarily to arsenic and to X-rays and radium, it has sooner or later been uniformly fatal.

Ætiology. It may occur at any age, but is most frequent in the 3rd and 4th decades. Males are attacked twice as often as females. In very rare instances two members of the same family have been affected.

Pathogeny. Various infective agents have been put forward as responsible: (1) A special form of tuberculosis was described by C. Sternberg (1898); Fraenkel and Much (1910) incriminated a granular form of the tubercle bacillus, and Ewing (1929), stating that "tuber-

culosis follows Hodgkin's disease like a shadow," appears to be in sympathy with this view. L'Espérance (1928) maintained that avian tuberculosis was responsible, but this has been vigorously contested (van Rooyen). Inoculation of animals with lymphogranulomatous material has given positive and negative results in different instances, and it is generally agreed that the positive reactions were due to secondary tuberculous infection of an already lymphogranulomatous gland. (2) Spirochætes have been described (White and Proescher, 1908), and dismissed (Gordon). (3) A pleomorphic diphtheroid bacillus theory was put forward by Yates and Bunting (1917), but has not been confirmed. (4) As the result of prolonged investigation, Gordon and his co-workers on "The Rose Research on Lymphadenoma" (1932) at St. Bartholomew's Hospital have brought forward much evidence in favour of extremely minute spherical or oval "elementary bodies" which have been photographed. (5) The disease has been regarded as a granuloma due to an unknown infection. (6) As a lymphoblastoma and allied to leukæmia. (7) As a transition between a granuloma and a new growth.

It seems probable that in addition to cases with a characteristic histological picture there is a gradation of atypical forms of the disease constituting the "Hodgkin group" (Gordon). The inclusive term lymphoblastoma has been employed to cover Hodgkin's lymphogranuloma, mycosis fungoides, leukæmia and lymphosarcoma. The portal of entry of the infection is unknown; but a possible one, the tonsil, is seldom affected.

Morbid Anatomy. The hæmatopoietic tissues, including the bone-marrow, undergo a cellular hyperplasia which is more like that of chronic granuloma than that of sarcoma. It is, however, remarkable that the lymphoid tissue of Peyer's patches and the solitary follicles of the small intestine and colon are so rarely affected. Cases of diffuse invasion of the walls of the gastro-intestinal tract, sometimes suggesting lymphadenoma, are usually histologically of a different nature, such as lymphosarcoma. The lymphatic glands are enlarged and discrete, on section present a greyish, somewhat gelatinous appearance, and may show yellow spots of necrosis but, unless secondarily infected, do not suppurate or, unless tuberculosis has supervened, show gross caseation. The capsules of the glands remain intact and are free from peri-adenitis in the absence of secondary infection, e.g. tuberculosis, or the supervention of Hodgkin's sarcoma. At first soft, the glands gradually become fibrous and hard. Though enlarged superficial lymphatic glands are usually the first indication of the disease and have therefore

been regarded as its starting point, there is a growing opinion that these glands are often outlying extensions of primary intra-thoracic infection, especially when the axillary glands are enlarged, or of primary intra-abdominal disease, particularly when the inguinal glands are the first noticed to be enlarged (Ewing; Symmers; Minot and Isaacs). In the neighbourhood of the enlarged affected glands new masses of lymphoid tissue develop as a compensatory measure, but in their turn become invaded by the morbid process. The spleen is almost always enlarged and usually contains whitish or yellowish areas around the Malpighian bodies (the "hard-bake spleen"); these masses do not show the central softening seen in the somewhat similar tuberculomata (fig. 2294). Masses of this nature are less often present in the liver and kidneys. The lungs occasionally show this infiltration either locally or diffusely. In the late stages the capsule of the lymphatic glands may be penetrated by Hodgkin's sarcoma, which may invade other structures such as muscle. In a small number of cases amyloidosis occurs without any other cause, such as suppuration or syphilis.

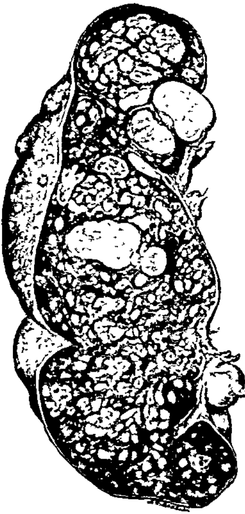

Fig. 2294.—"Hard-bake" spleen.
(*Museum, Middlesex Hospital.*)

The *histological* change in the glands, fully described by F. W. Andrewes, and independently by D. Reed, in 1902, is of practical importance, as on its presence certainty of diagnosis has long depended. In the earliest stage there may be a short-lived increase of the lymphocytes, but the important change is proliferation of the reticular and endothelial cells producing large pale cells with elongated vesicular nuclei, and resembling the epithelioid cells of the tuberculous large-celled hyperplasia of lymphatic glands. Multinuclear giant cells ("lymphadenoma cells"), quite different from those of tuberculosis

and from foreign-body giant cells, are the most characteristic of the varied cellular elements (fig. 2295). Eosinophil and plasma cells are also often, but not constantly, present, the eosinophil cells being probably brought from the bone-marrow, and not produced in the lymphatic glands. As time goes on, the glands show an increasing amount of hyaline fibrous tissue.

Clinical picture. In the vast majority of cases the first evidence of the disease is the painless enlargement of small, discrete, easily movable lymphatic glands, usually in the neck, especially just above the clavicle and in the posterior triangle (see fig. 2296). The glands gradually enlarge

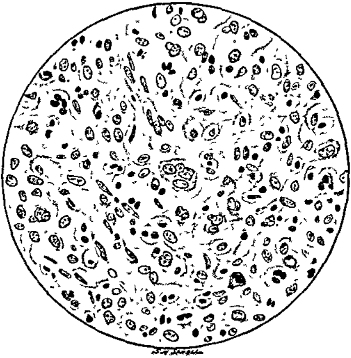

Fig. 2295.—SECTION OF A LYMPHATIC GLAND IN A CASE OF HODGKIN'S DISEASE. A MULTINUCLEAR GIANT CELL IS WELL SHOWN IN THE CENTRE OF THE FIELD.

and their extent spreads so that both sides of the body are affected. In some cases, however, pruritus precedes the appearance of any glandular involvement. The glands are soft at first, but later become hard and may diminish in size from fibrosis. Shrinking of the superficial glands, either spontaneously or after treatment, is not necessarily a good sign, for there may be concomitant extension and enlargement of the deeply-seated glands at the back of the abdomen and in the thorax. Enlargement of the spleen becomes more frequent as the disease progresses. Pressure symptoms from involvement of nerves, veins, the trachea and œsophagus may cause pain and loss of power, œdema, cyanosis, especially of the face, dyspnœa, displacement of the trachea, and dysphagia. Pressure on the spinal cord and the nerve roots may give rise to pain, paraplegia, and possibly herpes zoster.

Fever. Some febrile disturbance, especially of a mild character, is frequent, but the most important and remarkable is the relapsing or recurrent form. This was described by Murchison in 1870, and later by Pel (1885) and Ebstein (1887), hence the eponym Pel-Ebstein fever. It resembles the relapsing fever in some protozoan infections, such as rat-bite fever, but its span from the middle of one pyrexial period to that of the next is longer, from 15 to 25 or even 36 days (Hall and

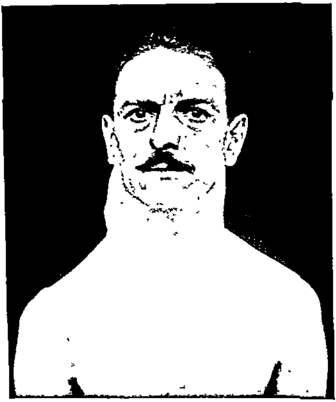

Fig. 2206.—Case of early Hodgkin's disease.
(*By courtesy of Mr. Cecil P. G. Wakeley*)

Douglas). The cause of the fever is not certain; it is not explained by secondary infections; but absorption of protein from necrotic foci in the glands has been suggested (Symmers).

Blood. In the earliest stage the red count may be normal, but later there is a progressive secondary anæmia of a chlorotic type which may become so severe as to necessitate transfusion. The white count does not show any constant or characteristic change. Usually there is not any leucocytosis, and there may be leucopenia with a relative lymphocyte increase. In a late stage when generalisation is rapidly taking place a polymorphonuclear leucocytosis has been described. Exceptionally, especially in the rare acute cases, there is an eosinophilia which may be very considerable, 70 per cent of the white cells even being

eosinophils; it has been thought to be a reaction in response to a foreign protein liberated from necrotic foci in the glands (Weber and Bode) which also causes pruritus and Pel-Ebstein fever. Mast cells may become obvious in the film.

Cutaneous manifestations of various kinds have been noted in about a quarter of the cases (Ziegler). Pigmentation may be due to the administration of arsenic, but may occur in its absence from involvement of the adrenals and of the sympathetic. Scratching due to pruritus may play a minor part in darkening the skin. Pruritus, thought to be toxic in origin, is the commonest cutaneous symptom; besides preceding any other evidence of the disease it may supervene in the late stages; it may be continuous, but is more often paroxysmal, be generalised or more rarely localised, and be accompanied by perspirations or by eosinophilia. The itching and the resultant scratching may be responsible for a prurigo-like papular eruption which consists in a small-celled infiltration around the sweat glands. Lichenification and pyogenic lesions may also be due to the scratching. A much rarer event is a true lymphogranulomatous infiltration of the skin, which must be distinguished from the less rare leukæmic infiltration, from sarcoids and sarcoma of the skin. Generalised exfoliative dermatitis and bullous eruptions have been recorded. Herpes zoster may be due to arsenical treatment.

Different forms of the disease have been described, according to its course—acute, chronic and latent—or according to its prominence in different parts of the body—generalised, thoracic, abdominal, splenic, hepatic, and a retroperitoneal form in which, except sometimes for splenic enlargement, there may not be any palpable tumour. Intrathoracic involvement may behave like a mediastinal tumour and cause dyspnœa, venous stagnation, cyanosis, and pleural effusion which may be chylous or chyliform.

Abdominal symptoms. Enlargement of the spleen is in rare instances an almost isolated sign, so that a splenic form has been described. The spleen is palpable in about 70 per cent of the cases. The liver is frequently and sometimes much enlarged, and an hepatic form has been described (Olmer). Abdominal symptoms, such as pain, heartburn and diarrhœa, may occur quite early in the course of the disease. In some cases the pain may be so severe as to imitate peptic ulcer. Pain in the lower part of the back may be correlated with enlargement of the retroperitoneal glands. Jaundice may be due to pressure on the bile-ducts and may be intermittent, corresponding with the glandular swelling occurring in the bouts of relapsing fever. Ascites may also occur.

Nervous manifestations. Murchison (1869) reported convulsions and delirium. Invasion of the intervertebral foramina by an extension from retroperitoneal glands may cause pain and, from pressure on the spinal cord, paraplegia. In extremely rare cases acute meningo-encephalopathy (Barker) has been described.

Complications. Generalised tuberculosis has been estimated to occur in a quarter of the cases (Ziegler). The relapsing Pel-Ebstein fever, which is not so rare as the recorded cases would suggest, and the transformation into Hodgkin's sarcoma may be regarded as complications.

Prognosis. So far as is known, the disease is invariably fatal, usually after a course of two to three years. Latent cases, in which little change occurs for some time after the detection of enlarged glands, have lasted ten or fifteen years, but, on the other hand, acute cases may terminate in a few weeks to two or three months. Cases showing the relapsing type of fever run a more rapid course than the ordinary cases, and the interval between the onset of this fever and death has been found to be about seven and a half months (Batty Shaw).

Diagnosis. The positive determination of the disease can be made by the demonstration of the characteristic histological changes in a superficial lymphatic gland removed as a routine. There is the fallacy that the gland removed may be one enlarged not by the presence of the disease but by hyperplasia compensatory for the destruction of lymphatic tissue elsewhere. It has been recommended that the glands selected for biopsy should be hard and fibrotic and not recently enlarged (Turnbull).

Gordon's biological test. Intra-cerebral injection of an emulsion of an affected gland into rabbits or guinea-pigs gives rise, after an incubation period of one to several days, to symptoms of encephalitis; this is not produced by similar injections of lymphatic glands with other morbid lesions. This test is chiefly valuable in the diagnosis of disease in an early stage, for glands from chronic cases may give a negative reaction.

Differential diagnosis must be made from forms of tuberculous adenitis and lymphosarcoma by means of a microscopic examination of an excised gland; from lymphoid leukæmia a blood examination should be decisive. Glandular fever might for a time suggest the onset of Hodgkin's disease. Retroperitoneal cases may imitate typhoid fever, which can be eliminated by agglutination tests. The splenic form may imitate chronic splenic anæmia, and the hepatic form when accompanied by fever may simulate hepatic abscess. Other forms of reticulosis should be distinguished by microscopic examination of a gland removed for diagnosis. The condition of splenomegalia lymphatica hypoplastica,

described by Brill, Baehr and Rosenthal (1924), showed remarkable hyperplasia of the lymphatic follicles and was extremely susceptible to irradiation.

Treatment. Arsenic, either by the mouth or by intravenous injection of arseno-benzol preparations, has earned a reputation for producing a remission, but glandular enlargement recurs and then often does not respond to arsenical treatment. X-rays exert a powerful influence in reducing the size of soft glands, and the patients may improve so much as to return to their ordinary life. But hard glands are little changed, and unfortunately glandular hyperplasia, after first subsiding under treatment, recurs and then usually fails to respond to irradiation as before. Cases with relapsing fever do not react to irradiation (MacNalty). Overdosage of X-rays may lead to generalisation and may shorten life (Minot and Isaacs), and doubt has sometimes been expressed if X-rays, though they certainly relieve the symptoms, appreciably prolong life. Radium has been much used and has been thought to be more effective than X-rays, and radon seeds have been employed. The remissions following radium therapy vary from 6 to 18 months.

Treatment by *irradiation* (X-rays or radium) combined with mixed toxins of erysipelas and *bacillus prodigiosus* (Coley's fluid) gave rise to considerable remissions in Coley's hands.

Specific treatment, such as the injection of serum from chickens inoculated with suspensions of the lymphogranulomatous glands, has been tried. A sensitised vaccine of the " elementary bodies " (Gordon) has given very encouraging results in early cases (Warner); but more experience of this treatment is essential.

Surgical treatment should be employed as a palliative measure only, for example, to relieve pain or to remove pressure on the trachea. Extensive dissections, such as were originated for carcinoma of the breast by Halsted and Crile, are likely to be disappointing, as affected glands may escape removal.

Generalisation of the disease may follow operations on the enlarged glands, or even a biopsy, but rapid spread may have begun before, and been responsible for the symptoms leading to operative interference. Some writers, however, such as Minot and Isaacs (1926), consider that early removal supplemented by irradiation is probably of definite benefit.

CHAPTER VII

Glandular Fever

by

Charles R. Box

Glandular fever (Infectious Mononucleosis) is an acute febrile and infectious adenitis with a characteristic increase in the mononuclear cells of the blood. The course is benign; complications are rare. The disease was first observed in children by Pfeiffer who described it in 1889, under the name of " Drüsenfieber." Apart from an observation by Türck in 1907, and the report of a few cases of alleged lymphatic leukæmia with recovery, it was nearly thirty years before a striking blood picture was noted by Sprunt and Evans and by Longcope in an infectious angina which was not, however, then identified as glandular fever. This identification we owe to Tidy and Morley in 1921.

Glandular fever is thought to be a virus infection, although J. O. W. Bland, as the result of transmission experiments, believes it to be due to a protozoon. There is no convincing evidence that Vincent's organisms can cause the disease as some have surmised. The throat, the respiratory tract, and perhaps the bowel are the portals of entry. The mononucleosis is distinctive, and the assumption that this is due to individual idiosyncrasy is disproved in that the same individual reacts to other infections by a polynuclear leucocytosis.

Glands have often been excised for examination. They are discrete, encapsuled and greyish-white. The cut surface is homogeneous and glistening, with perhaps a few petechial hæmorrhages. Microscopically the normal structure, although distorted, is still discernible. The germ centres are hyperplastic and infiltrated with large, pale, oval or polygonal cells, many of which have lobulated or indented nuclei like the cells found in the blood. This hyperplasia of the reticulo-endothelial system is the outstanding feature.

The disease may occur in localised epidemics; sometimes it is more widespread, but many isolated cases occur, and it is with these that diagnosis may be in doubt.

Infectivity is slight and its duration appears to be very short. The

incubation period is from 5 to 15 days, usually about a week. More males than females are attacked. No age is really exempt, but most attacks occur in school children and young adults. Up to the age of 15 years glandular swelling is the prominent feature, but in adults the infection is apt to show itself as an obscure fever identified after a variable period by the supervention of adenitis. Sometimes faucial inflammation is unusually pronounced, its nature being finally elucidated by detection of the characteristic mononucleosis.

Onset in the younger patients is usually with febrile symptoms of no great intensity, and slight soreness of the throat. The tongue may be furred and the bowels confined. Sometimes invasion is more severe, with shivering, vomiting, headache, or even delirium. Sweating and epistaxis may occur. Prodromal symptoms usually last for a day or two before the glandular swelling appears, but they may be so slight as to escape attention, in which case the adenitis or consequent stiffness of the neck may first call attention to the illness.

In a typical case the adenitis is most pronounced in those glands of the carotid chain which underlie the upper half of the sterno-mastoid muscle. It is often unilateral at first and frequently left-sided. In degree it is quite out of proportion to the trivial faucial inflammation, but sometimes a follicular or even a membranous exudate appears on the tonsils, constituting an anginous variety of the disease. The cervical swelling is rapid and painless, the conglomerate glands forming a visible tumour the size of a pigeon's egg or larger below the angle of the jaw. Accompanying fever ranges from 101° to 103° F. or more. The swelling is elastic and tender, but there is rarely any redness or œdema of the overlying skin. Suppuration is very exceptional.

The cervical adenitis is often a part of a widespread but insignificant enlargement of glands in other parts of the body, such as the posterior triangles of the neck, the axillæ, groins and epitrochlear regions. These glands are discrete, mobile and painless. Occasionally the brunt of the disease falls on the bronchial or mesenteric glands, giving rise to distinctive types known as thoracic and abdominal. In the former, a paroxysmal cough simulates pertussis, and dysphagia may occur; in the latter, abdominal pain may mimic appendicitis. Sometimes the enlarged mesenteric glands can be felt.

Enlargement of the spleen is the rule rather than the exception, the edge being palpable an inch or more below the costal margin. In some cases the liver is enlarged as well.

A sparse and ill-defined eruption may be present on the trunk but is exceptional in this type of the disease; in some cases it suggests

typhus or typhoid fever, in others measles. In fulminant cases cutaneous petechiæ have been observed on the legs and trunk.

The fever after a few days becomes intermittent in type, and usually subsides within a fortnight, but may persist for several weeks. The pulse-rate is not unduly rapid, and it is only in prolonged attacks that signs of cardiac weakness have been observed.

As a rule, the glandular enlargement outlasts the fever, resolution being slow. Rarely, it only appears when the fever has subsided. The disease may in some instances progress by stages, one group of glands becoming enlarged as another subsides.

With the recognition of the diagnostic significance of monocytosis, an adult type of the disease was described in London and its neighbourhood in 1930. This differs in incidence and course from the juvenile type described above. The onset may be sudden or insidious. The outstanding clinical features are:

Adult incidence; prolonged fever of a type suggesting typhoid infection; a scanty maculo-papular eruption on the trunk at the end of the first or beginning of the second week, and a delay of two or even three weeks from the onset before the glandular swellings appear. The glands are not so prominent as in the other type of the disease. The onset of monocytosis is mostly coincident with the glandular swellings, as also may be the detection of splenic enlargement. A peculiarity is the development of a transient Wassermann or Kahn reaction in the blood. Recrudescences or relapses may occur, but recovery is the rule.

The blood picture of glandular fever shows a striking increase in the mononuclear cells. This sets in some days or, in the adult form, even a week or two after the onset. It may only occur when the glandular enlargement has become pronounced. There is no marked anæmia and no platelet reduction. The leucocyte count may reach 40,000, but it is seldom above 20,000 and often only 10,000 per c.mm. Of the total white cells the lymphatic or mononuclear varieties average 40 per cent, but may increase to 90 per cent in some instances. Three varieties of these cells may be recognised in the smears: (1) Small lymphocytes, as in normal blood; (2) large mononuclear cells, also resembling those of normal blood; and (3) aberrant cells, which usually preponderate, larger than the small lymphocyte, with an indented or lobulated nucleus, and a varying complement of azurphil granules. The protoplasm is deeply basophil and may be vacuolated. These atypical cells have been regarded by some as lymphoblasts, but others note their resemblance to plasma cells. The oxydase reaction which

occurs solely in granule-containing cells of the myeloid series is negative. The granular white cells of the smears average 10 to 20 per cent and there may be a shift to the left so that a few myelocytes appear. Eosinophils and mast cells are present.

The duration of the mononucleosis is extremely variable; in some cases it persists for months, in others it is transitory. Unless several counts are made at short intervals it may be missed entirely.

Sufferers from glandular fever develop in their blood serum heterophil anti-bodies against the red corpuscles of sheep. This is the Paul-Bunnell reaction. It becomes positive with the appearance of the swollen glands. A titre of 1 in 100 is diagnostic.

Complications are very few, but convalescence may be tardy. A slight temporary albuminuria with tube-casts may occur, and in some 6 per cent of the cases hæmorrhagic nephritis ensues. Suppurative otitis media and retropharyngeal abscess have been recorded. In exceptional cases, chiefly those with marked faucial infection, the cervical glands suppurate. Broncho-pneumonia and collapse of lung have been seen.

Diagnosis. During an epidemic diagnosis should not be difficult, but isolated cases give rise to doubt because slight sore throat with secondary enlargement of the glands of the neck is a very common event. When the typical blood count is available this is characteristic, stress being laid on the marked increase in the plasma type of cell.

When faucial inflammation is pronounced, other forms of tonsillitis and certain infectious fevers must be excluded. Bacteriological examination is important and will certainly detect diphtheria. The frequent detection of Vincent's organisms in glandular fever has already been commented on. The possibility of a primary syphilitic infection of the lips, tongue or fauces should be remembered. Acute septic tonsillitis of streptococcal origin may give rise to a rapidly swelling adenitis of the tonsillar and other glands of the deep cervical chain, with prostration, high fever and perhaps rigors, but there is generally a polynuclear leucocytosis. Agranulocytic angina is distinguished by the disappearance of all granular elements from the blood.

Differentiation from mumps should be easy, despite the accompanying lymphocytosis. The statement that the salivary glands may swell in glandular fever is an error, although the disease has been described as "aberrant mumps." Lymph glands may overlie the submaxillary and parotid glands and be mistaken for them.

In German measles the cervical, and especially the mastoid and

occipital, glands may be enlarged and tender for some days before the distinctive rash appears, after which, as a rule, they quickly subside. After the eruption a leucopenia may be found, which is maximal on the third day. The number of polymorphonuclear cells is diminished, but the proportion of Türck cells and of plasma cells is said to be higher than in any other infectious disease. Within a week or two the blood becomes normal.

Whooping-cough may be simulated when the bronchial glands are enlarged, and moreover in whooping-cough there is a lymphocytosis with a high percentage of small lymphocytes. Detection of palpable superficial glands is in favour of glandular fever, whilst presence in the sputum of numerous slender Gram-negative bacilli points to whooping-cough.

Fevers of the enteric group may be simulated if pyrexia is prolonged before the adenitis appears. Diagnosis will depend upon the clinical course of the disease, coupled with blood culture in the early stage, bacteriological examination of the urine and fæces, and on the appropriate agglutination reactions. A transient initial leucocytosis followed by leucopenia with a relative lymphocytosis is characteristic of typhoid and paratyphoid fevers. A few cases of glandular fever have shown a misleading agglutination with typhoid " O " antigen in low titres. On occasions abortus fever has been accompanied by rather pronounced glandular enlargement.

Differentiation from acute leukæmia may be difficult. In this disease fever, buccal inflammation, glandular swellings and leucocytosis are evident, but one type of lymphocyte or immature cell forms the bulk of the white cell increase. Progressive anæmia, diminution of blood-platelets, hæmorrhagic tendency and rapid downhill course are important diagnostic points. There is little doubt that cases of recovery from acute leukæmia, from time to time reported, are really examples of glandular fever or infectious mononucleosis. The rare disease, monocytic anæmia, is distinguished by a heavy percentage of large hyaline leucocytes.

The sub-acute type of glandular fever, with recurrent glandular swellings, sweats, and irregular exacerbations of fever may resemble Hodgkin's disease closely, but the blood picture and ultimate course differentiate it. Microscopical examination of an excised gland is valuable in doubtful cases.

Tuberculous adenitis is distinguished by its greater chronicity and by a tendency to peri-adenitis, softening and involvement of the skin. Blood changes are inconstant, but signs of tuberculosis may be found elsewhere.

Stiffness of the neck, caused by tender, swollen glands, may lead to

suspicion of early spinal caries. This is negatived by detection of the tender glands and the absence of radiological evidence of bone disease. The occurrence of the characteristic blood picture and the transient nature of the symptoms will establish the true diagnosis.

The abdominal symptoms of glandular fever have not infrequently led to operation for appendicitis. Detection of enlarged accessible glands, a palpable spleen, and the nature of the blood changes should prevent mistake. At operation lymphatic hyperplasia of the appendix and markedly swollen lymph glands should arouse suspicion as to the nature of the case.

Treatment is symptomatic. Ultra-violet radiation is said to speed up the disappearance of the glandular swellings. In protracted cases injection of the blood serum of a patient convalescing from glandular fever may bring the disease to a termination.

Infectivity apparently ceases before disappearance of the clinical signs of the disease. Isolation for seven days after the subsidence of the fever and glandular swelling has been recommended in acute cases.

CHAPTER VIII

The Significance and Differential Diagnosis of Lymph-Gland Enlargement

by

R. Sleigh Johnson.

Affections of the lymphatic system, by their frequency of incidence and variability in type, afford one of the common meeting-grounds of medicine and surgery.

In a case of glandular enlargement, blood diseases, factors of constitutional type, infections, specific or otherwise, and new formations may all need consideration in their possible relationship, apart from more localised and directly surgical conditions. In a text-book of surgery it may not, therefore, be out of place to review some of the more important features of lymph-gland enlargement in general, with special reference to ætiology and differential diagnosis.

In any such consideration it must be borne in mind that lymphoid tissue is not confined in its distribution to the lymph "glands" (or lymph "nodes" as they are more correctly defined), but is present extensively throughout the body in other organs, notably the spleen, thymus and tonsils, of which structures it constitutes the larger part, as well as being scattered throughout the mucous membrane of the pharynx and lower intestinal tract. Any generalised affection of the lymphatic system involving enlargement of groups of lymph nodes is in accordance commonly reflected in an accompanying proliferation or other histological change in the lymphoid tissue of one or more of these latter structures.

Besides providing in their germinal follicles the main source of supply to the body of lymphocytes, lymph nodes have the further important function of constituting a line of defence against infection arising within the area of their drainage. Commonly directed against bacterial invasion, this resistance may in other cases be concerned with a variety of foreign substances, or with malignant or abnormal tissue cells, the aim in each instance being the prevention of a general blood-stream involvement. In this process, whatever its specific pathology, the affected nodes become enlarged and clinically apparent. With

regard to clinical examination, it may be said that, unless there is generalised wasting, a palpable lymph node is a pathological one, though perhaps only from repeated minor sub-infection, the anatomical situation of the various groups of nodes being such that they normally lie hidden and impalpable in protective fat or connective tissue.

The *differential diagnosis* in a given case of lymph-node enlargement will follow from a consideration of the undermentioned main aspects of the case:

(1) The distribution of the enlargement, i.e. which group or groups of nodes are affected.
(2) Possible abnormality in the area or areas of lymphatic drainage.
(3) The physical characters of individual enlarged nodes.
(4) *Affection of other lymphoid structures.*
(5) Evidence of general systemic disturbance, and if present its nature.

Each of these aspects may be further considered. Of primary importance is the determination as to whether the involvement of glands is a local process or whether the enlargement is a generalised one. Accordingly, in any case of glandular enlargement, even where apparently localised to a single gland or group of glands, a brief general survey of the common main lymphatic zones should be made; if carried out as a routine, palpation in turn of the cervical, axillary and inguinal regions will help to avoid the error of confusing local with general systemic disease, and takes but little time; moreover, in multiple enlargement one such zone frequently dominates the picture. If only local enlargement is detected, the possibility of a general systemic condition is made less likely but not excluded, and special pathological investigation may in some cases still be required. No detailed note is called for here regarding the detection by inspection and palpation of enlarged glands in the common superficial areas, except perhaps to stress the need for the fullest relaxation by suitable posture of the limb concerned, and to comment on the masking of enlarged glands which sometimes ensues in inflammatory cases from associated muscular rigidity and reflex spasm. Reference may also be made to the possible detection by deep palpation of enlarged glands within the abdomen, whether lying in the mesentery, usually having some range of mobility, or situated more fixedly in the deep iliac or aortic areas. As with other abdominal swellings, preliminary purgation may be required in doubtful cases, and, if the circumstances warrant, a confirmatory examination under anæsthesia. In some special cases the presence of enlarged glands may in impalpable

areas be suspected or inferred from accompanying pressure effects peculiar to their position, e.g. jaundice and ascites from enlarged glands in the portal fissure. The value of X-ray investigation of the abdomen, as for suspected tabes mesenterica, is limited, seeing that only those glands will be revealed in which the tuberculous lesion has healed by calcification, while more active disease shows no comparable opacity and is likely to give negative or inconclusive results.

A further region where enlargement of important groups of glands is similarly obscured is within the thorax, and in any suspected condition in which generalised glandular enlargement is known to occur this site also should be investigated. A number of intricate physical signs are described from which enlargement of the tracheo-bronchial glands is to be deduced, but it may be affirmed that these are of no clinical value unless the swelling of glands be of a gross order. Even so, such signs as are produced result commonly not from the mass of glands *per se*, but from their pressure effects upon adjacent lung tissue, producing pulmonary collapse, or upon lymphatic vessels and veins in the posterior mediastinum or lung roots with ensuing pleural effusion, distension of surface veins, and perhaps œdema of the chest wall, upper limb or face. With such enlargement of this group of glands, impairment or dullness may be found in the inter-scapular region or at the lung base, with weak or altered breath sounds. This cause of unexplained pleural effusion or obscure swelling (from œdema) of one breast is therefore to be kept in mind. Gross enlargement of glands in the anterior or superior mediastinum may similarly be shown by dullness anteriorly, perhaps with a visible swelling and evidence of pressure upon the air-passages or veins and nerves of the head and neck.

In some cases the effects described are due not directly to enlargement of the glands themselves, but to involvement of adjacent organs, such as the lung, in an infiltrative spread of the same disease-process; examples are found in carcinoma and, rarely, in Hodgkin's disease. Again, the degree and nature of pressure effects will vary with the underlying pathology, being proportionately greater with a neoplastic than with an inflammatory cause.

Confirmation of gross clinical enlargement, and diagnosis of lesser degrees of enlargement, are in all cases dependent upon X-ray examination of the thorax. Oblique and lateral films will be required in addition to antero-posterior, and heavy exposure may be needed, using a Potter-Bucky diaphragm. Opportunity for investigation should not be deferred until the X-ray picture may have become obscured by secondary pulmonary or intra-pleural events.

A preliminary examination on the lines given will have decided into which category the glandular enlargement falls, whether *local* or *generalised*. If the former, scrutiny is then directed towards the area known to be drained by the group affected, for evidence of primary disease. If present, this is likely to be inflammatory or neoplastic; if inflammatory, it may be acute or chronic; if neoplastic, it is commonly malignant, although pyogenic infection of an innocent and perhaps ulcerated primary growth may give rise to a misleading inflammatory enlargement of the corresponding group of glands.

In *acute inflammatory lymphadenitis* the primary lesion is usually clear: the glands are tender, soft, discrete at first, later perhaps becoming fixed, ill-defined, and confluent from surrounding peri-adenitis and œdema or suppuration with local redness and softening of the skin. One or more glands only of the group may be involved, and that to a differing degree. Lymphangitis proximal to the glands may also be present, with evidence of general intoxication and a leucocytosis.

Chronic pyogenic infection is the commonest cause of localised glandular enlargement, especially of the cervical group, because of the wide prevalence of minor chronic infections of the mouth, ear, nose and throat, or scalp. As contrasted with acute inflammation, there is less tenderness on palpation, while the degree of enlargement is seldom as marked and the glands tend to remain discrete.

Next to pyogenic infection, the most frequent cause of a localised chronic inflammatory lymphadenitis is *tuberculosis*, and again the neck is the usual site, predominantly the anterior triangles. At first discrete, mobile, firm and painless, without tenderness on pressure, with extension of disease through the gland capsule adhesion of glands occurs, both one to another and to adjacent tissues, forming an irregular confluent swelling with less range of movement. Central caseation and liquefaction tend to produce softened fluctuating areas with eventual adhesion to the skin, the thinning and breaking down of which leads to sinus formation and external scarring. A history of contact with a tuberculous patient, and the finding of a positive Mantoux reaction will assist diagnosis at an earlier stage.

Local enlargement of glands secondary to *malignant disease* occurs most frequently from infiltration with carcinoma. Such glands are in themselves completely painless and insensitive to pressure, stony hard in consistency, with early fixation to surrounding structures, and usually appear in the anatomical zone drained by the primary growth. Similarly, secondary sarcomatous glands may form large coalescent masses with like features, although usually of softer texture. Of primary neoplasms arising in lymphatic glands the most important type, namely, lymphosarcoma, shows early tendency to generalisation, and will therefore be discussed with the group of multiple gland enlargement. The same consideration applies to the less common types of chronic inflammatory adenitis, such as Hodgkin's disease and syphilis.

The need has already been stressed in the differential diagnosis of localised lymph-gland swelling for a search for the primary focus of disease, whether inflammatory or a new growth. This latter is not, however, always to be found, and for two reasons. In the first place, infection may have been through a minute

point of entry, the surface abrasion healing while the disease becomes manifest within the glands. Alternatively, and especially with neoplasm, the initial lesion may be situated in some obscure internal part of the body not obvious on surface examination, e.g. the œsophagus, prostate or some deep-seated abdominal organ. Lack of discovery of a primary focus on first examination does not accordingly exclude its presence.

Where swelling of lymph glands is found on examination to involve more than one lymphatic region, investigation is extended to the known causes of *generalised enlargement*. Here a detailed study of the history of illness and a full physical examination of the patient are required. The possible causes may be considered under the headings *acute* and *chronic*, although the division is an arbitrary one.

Concomitant evidence of *acute infection* may be found in general malaise, fever of recent onset, and perhaps a rash, while differential diagnosis is helped by the age of the patient, the situation and character of the enlarged glands, and by special pathological tests.

An acute febrile illness in a child or young adult, having as its main clinical feature a painful enlargement of cervical glands, is likely to be due to *glandular fever* (see also page 4227). In its usual form, this is ushered in by a short prodromal period with fever of 102°–103°F., when enlargement of glands becomes evident in characteristic situations, the commonest being the deep posterior cervical group behind the middle and lower half of the sterno-mastoid, at first confined to one or other side. The enlarged glands remain discrete and mobile, are firm and elastic in consistency, and tender sometimes to the extent of producing torticollis or head-retraction from reflex spasm. With full development of infection, the glandular enlargement spreads in most cases to the axillary groups, and less often to the inguinal and epitrochlear glands. Frequently the mediastinal glands also may be involved, causing an unproductive irritable cough, and the mesenteric with abdominal pain and tenderness, while a slight degree of splenic enlargement is found in over half the cases. The glandular swelling may subside, together with the accompanying fever, within a few days, but not uncommonly both persist for several weeks or rarely months, while general debility and slight tender enlargement of glands may remain for a like period. Breaking down of glands is never seen in glandular fever, but relapse is apt to occur. Less often, soreness of the throat is a prominent feature of the infection. Typically, no rash is present, a point of diagnosis from rubella, but rarely a prodromal maculo-papular eruption has been described before the stage of glandular enlargement.

The diagnosis of glandular fever is clinched by the characteristic blood changes, and a full blood count should be made in any suspected case. Anæmia is not a feature; the total leucocyte count is usually raised to a moderate degree, not often above 20,000, but the striking and pathognomonic feature is the high preponderance in the differential count of mononuclear cells. These may reach a proportion of from 60 to 80 per cent of the total count, and are made up of a variety of types, normal lymphocytes, primitive lymphocytes, monocytes, endothelial and plasma cells. Where opportunity has arisen, examination of excised glands has shown a similar histological change, with hyperplasia of the lymphoid tissue and reticulo-endothelial elements. The characteristic blood changes described have led to the alternative naming of glandular fever as "acute infective mononucleosis." Infectivity is mild but definite, with incubation period of about a week.

Epidemic outbreaks are not uncommon and, as such, afford a point in favour of the diagnosis. The chief difficulties in diagnosis are from rubella and from acute lymphatic leukæmia. The former, as noted below, has a characteristic rash. In the latter condition illness is usually much more marked, and dominates the picture, while the total leucocyte count is greater, with progressive anæmia. A diagnostic fallacy must be mentioned with regard to glandular fever, in that in about half the cases the Wassermann reaction becomes temporarily positive. A specific agglutination test for glandular fever is now, however, available, giving positive reactions up to a dilution in some cases of 1 in 4000 of the patient's serum at the end of the third week of illness.

A further acute condition with glandular enlargement which may simulate glandular fever is *rubella*. Also occurring in the early decades, it is shown by slight or moderate febrile disturbance, with enlargement of the sub-occipital, mastoid and posterior cervical glands on each side. These are firm, discrete and tender, evident by palpation only, and seldom if ever reaching the degree of swelling found in glandular fever. The axillary and inguinal groups are sometimes enlarged, and rarely the spleen is palpable. Mild catarrhal symptoms are present, and the diagnosis is made clear by a characteristic skin eruption, beginning as rose-pink macules on the face and behind the ears and rapidly spreading over the trunk to coalesce into a widespread erythema. Both rash and adenitis are of short duration, a matter of days only. A leucopenia is the rule in the blood.

A painless discrete enlargement of glands in the posterior triangles of the neck, of rubbery consistency, moderate degree and symmetrical distribution, suggests the possibility of *secondary syphilis*. Malaise and a mild degree of fever are commonly present. Suspicion would be confirmed by the finding of mucous patches in the mouth or throat, condylomata, characteristic maculo-papular rash, or primary chancre, and the diagnosis established by a positive Wassermann or Kahn reaction in the blood. Enlargement of the epitrochlear glands also is often present, occasionally accompanied by slight enlargement of the axillary and inguinal glands and of the spleen. This glandular enlargement of the septicæmic stage of syphilis tends to outlive the majority of other secondary manifestations of the disease.

The clinical combination of glandular enlargement with acute febrile illness and a high and progressive degree of anæmia raises the suspicion of an *acute leukæmia*. In this condition the patient, usually under the age of twenty, shows a generalised enlargement of glands, often not great, with striking or extreme pallor, a high degree of fever, often 103°–104° F., and almost invariably an acute ulcerative or phagedænic condition of the mouth and throat. Purpuric hæmorrhages with widespread bleeding from mucous surfaces add to the picture. Slight or moderate enlargement of the spleen is usually found, although in some cases the swelling of both spleen and glands may be minimal. The course of the illness is invariably downhill to a fatal termination within a few weeks. The symptoms described should lead to examination of the blood, by which means the diagnosis is established. A marked secondary anæmia is found, often with liberation of nucleated red cells;

the total leucocytes are commonly increased to a moderate degree, as from 20,000 to 40,000, although the very high white counts of chronic leukæmias are rare. Exceptionally a leucopenia is found. The white cell showing excessive proliferation and responsible for the leukæmic state is most often a myeloblast, although formerly, through an inadequate investigation of staining reactions, these cases were all thought to be examples of acute lymphatic leukæmia. Staining for oxidase granules enables the myeloblast to be distinguished from the large lymphocyte which it otherwise resembles. A true acute lymphatic leukæmia of small lymphocyte type does also occur. There is little or no clinical distinction between the various types. In considering differential diagnosis, the enlarged glands, fever, and palpable spleen, or sometimes liver, may in the initial stages suggest glandular fever. As already noted, however, in acute leukæmia the degree of general disturbance is far more severe, and often such as to render the lymphatic enlargement inconspicuous by comparison. The texture of the glands is moreover softer than in glandular fever. In addition, the pleomorphic nature of the leucocytic response in glandular fever contrasts with the increase in a single type of cell in a given case of acute leukæmia.

A further condition of acute illness with glandular enlargement in children, sometimes causing confusion with glandular fever, has recently been described by H. C. Cameron and by R. M. Miller under the term "*epidemic streptococcal adenitis.*" Abrupt fever follows a mild transitory sore throat, with much prostration and rapid painful enlargement of the tonsillar, cervical, and even occipital glands. These may become greatly enlarged, hard, discrete and tender, with muscular rigidity, rigors and sweats and a tendency for one or more glands to break down and suppurate. From such discharging glands a pure culture of hæmolytic streptococcus has been obtained. Other distinguishing features from glandular fever are a polymorphonuclear leucocytosis rather than an increase of lymphocytes, negative agglutination reactions, and an absence of involvement of the spleen or other groups of glands.

Chronic generalised glandular enlargement. Where a long-standing or insidious enlargement of multiple groups of glands is found, the differential diagnosis lies in the main between *chronic granulomatous forms of adenitis*, *primary blood diseases*, and *new growths*.

Of the *chronic inflammatory affections* the most important, and often the most difficult of precise diagnosis, is *lymphadenoma or Hodgkin's disease* (see also page 4218).

Formerly the subject of much difference of opinion as to whether it was to be regarded as inflammatory or neoplastic in nature, it is now considered by most to be a specific granuloma, a view supported by the coexistence of fever, sometimes of periodic type, the occurrence of natural remissions, the blood picture and the histological features of the glands and other affected tissues. The disease is met with most often, but not invariably, in adolescence and early adult life, and predominantly in the male sex. *An insidious and painless enlargement of glands*, usually on one side of the neck, commonly brings the patient under observation, disturbance of the general health at this stage being slight or even absent. There are, even at this phase, specific clinical features of the glandular enlargement which are of help in suggesting its likely nature. The glands of a group become markedly enlarged, often all in the group to an approximately equal degree, and although forming an obvious swelling, yet the individual glands remain quite discrete from one another and preserve their free mobility, becoming adherent neither to the skin nor to deeper structures. They are initially soft, becoming firm and rubbery, or finally hard from increasing fibrosis with the progress of the disease or as a result of treatment; they are not at any stage painful or tender. Although starting in one area, the tendency to a progressive and orderly spread of glandular involvement to other zones is great, it being the rule rather than the exception when a case is first seen to find evidence of enlargement in most or all of the common superficial areas. With this spread there is accompanying degeneration of general health, wasting, secondary anæmia, pigmentation, pruritus, and fever, sometimes of a periodic relapsing or Pel-Ebstein type of diagnostic significance. A firm moderate enlargement of the spleen is present, and often evidence of simultaneous affection of mediastinal and abdominal glands. Signs of visceral infiltration, as of the lung or liver, may in some cases also be found.

It has been noted that the common path of entry of the infection is via the cervical glands, where the most marked enlargement is therefore often found. Sometimes the initial site of enlargement, however, is one or other axilla or groin. Rarely, a patient may first come under observation with signs and symptoms of deep glandular involvement in the chest or abdomen, and in these cases great difficulty arises in differential diagnosis from lymphosarcoma and other similar tumours, owing to the absence of a removable gland for section. Fever and constitutional disturbances are found, but their cause may not be evident until X-ray examination reveals the deep-seated glands. In other cases, evidence of pressure on the air-passages or nerve trunks may accompany the general symptoms, or if the disease be apparently primary in the abdomen colicky pains and vomiting may call attention to the local enlargement. Jaundice and ascites may sometimes occur. If the likely diagnosis is not suggested by the general features of illness at this stage, involvement of peripheral groups of glands will eventually aid in revealing the condition.

The striking and helpful feature of lymphadenoma in diagnosis is its eventual tendency to widespread involvement of lymphatic structures, as also of other organs. Many such may show a granulomatous infiltration; the skin may be affected, producing palpable nodules; the spinal cord may be compressed from erosion of bony vertebræ; and the kidneys, stomach and intestines be infiltrated apart from the more usual involvement of liver and spleen.

Differential diagnosis is frequently difficult. The likely conditions from which

it must be distinguished are the chronic leukæmias, lymphatic or myelocytic, including their occasional aleukæmic phases, lymphosarcoma, and chronic tuberculous adenitis. Most help is obtained from blood examination and from study of the histology of a suitable gland removed under local anæsthesia.

There is no characteristic blood picture in Hodgkin's disease. The usual findings are a variable, perhaps marked, degree of secondary anæmia with a moderate polymorphonuclear leucocytosis. An absolute eosinophilia is sometimes present, the more so if the case be acute, but is on the whole so inconstant as to be of no value in diagnosis.

Greater help is obtained from biopsy, which may indeed afford the only decisive means of differential diagnosis from lymphosarcoma or tuberculosis, especially in those cases where a single large mass of glands predominates. Even so, it is important to choose for removal one of the less indurated glands of the group, as a densely hard gland is likely to show only the final stage of fibrosis from retrogressive changes and not the typical histological appearances of the active disease.

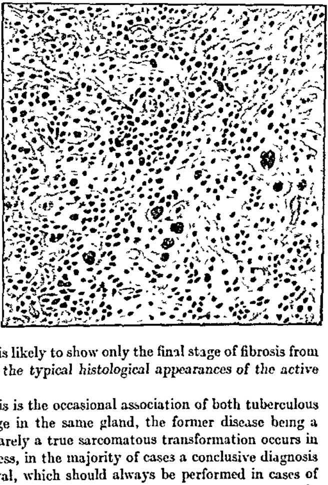

Fig 2297.—Histological appearance of lymphatic gland in lymphadenoma.
(*Dr. L. T. Bond's case.*)

Another fallacy in diagnosis is the occasional association of both tuberculous and lymphadenomatous change in the same gland, the former disease being a secondary infection. Again, rarely a true sarcomatous transformation occurs in Hodgkin's disease. Nevertheless, in the majority of cases a conclusive diagnosis may be made by gland removal, which should always be performed in cases of doubt. The changes found vary in detail, but typically embody the following main features: the normal lymphoid structure of the gland undergoes atrophy of varying degree and is replaced by numerous large, irregularly shaped, pale-staining reticulum cells with single rounded or oval nuclei; scattered among these reticulum cells (or "endothelial" cells) are less numerous and larger multinucleated cells, of characteristic form, having perhaps three to six nuclei which overlap one another within the cell or are arranged in a horseshoe-shaped pattern. Through-

out the gland structure is a diffuse overgrowth of the fibrous stroma, and scattered among the remaining cells are numerous cells filled with coarse eosinophil granules (fig. 2297).

M. H. Gordon in searching for a causative virus of lymphadenoma has shown that the intra-cerebral and intravenous injection into a rabbit or guinea-pig of a broth-suspension of macerated lymphadenomatous gland-tissue, after preliminary filtration, produces in the animal a specific meningo-encephalitis, whilst extracts of glands with other pathological lesions such as lymphosarcoma or leukæmia fail to do so. This would appear to provide then a further and more delicate test for the disease.

Occasionally difficulty in diagnosis from lymphadenoma arises with the uncommon form of *generalised tuberculous adenitis* met with more often in the older patient, with slight or moderate enlargement of the glands in the neck, axillæ and groins, little tendency to caseation or disturbance of health, and greater proliferation of endothelial cells than is usual in tuberculous lesions. The diagnosis is made by removal of a gland and staining for tubercle bacilli, which are usually to be demonstrated.

Lymphosarcoma, being a rapidly fatal disease, is fortunately one of the least common of glandular affections. It may, from its nature, arise in any region of the body containing lymphatic tissue, either within a group of lymphatic glands themselves or in an organ composed of, or normally containing, lymphoid deposits. When originating in a peripheral group of glands. there is a tendency for the growth to form one or more large irregular masses, with early and dense fixation to skin and deep structures. The glands are insensitive and less firm in consistency than are those of lymphadenoma. There is also greater variability in the size of individual glands of a group, as well as in the comparable degree of enlargement of different groups of glands. The severity of illness is, moreover, greater, and anæmia more rapid. Apart from direct infiltration of adjacent tissues, the liability of extension to neighbouring groups of glands, as well as to deep internal glands. is marked. Signs of mediastinal obstruction or pleural effusion are frequent, and large abdominal masses may be felt, from involvement of retroperitoneal or mesenteric glands and from matting and infiltration of intestines. Enlargement of the spleen is found in some cases. Alternatively, and more commonly, the disease may arise primarily within the thorax or abdomen or from lymphoid structures of the pharynx; of these the thymus and the tonsil may be mentioned as examples.

The degree of malignancy in these tumours varies with their detailed histology; in all, the liability to a progressive direct local and lymphatic spread is great and is the more usual course than widespread blood metastasis. Diagnosis from Hodgkin's disease and from other malignant growths can be made with certainty only by microscopic section.

Microscopically, lymphosarcomatous tissue is found to consist of an aggregation of small round cells with scanty cytoplasm and deeply-staining nuclei showing evidence of mitosis and division. Larger cells of endothelial type with convoluted nuclei may also be present, whilst a delicate supporting reticulum accompanies the proliferation, showing many newly-formed blood-vessels and a tendency to necrosis and hæmorrhage. Active infiltration is found through the capsule of the glands into adjoining tissues (fig. 2298).

The remaining common group of cases of multiple gland enlargement to be considered in differential diagnosis is the group of *chronic leukæmias*. In these conditions the patient, usually in middle or later life, comes under observation, not commonly with complaint of

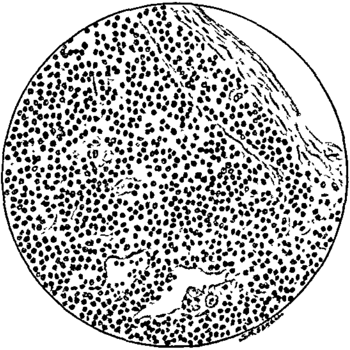

Fig. 2298.—HISTOLOGICAL APPEARANCE OF LYMPHATIC GLAND IN LYMPHOSARCOMA

lymphatic swellings, but rather with symptoms of anæmia or of heaviness and discomfort in the upper abdomen associated with great enlargement of the spleen. Well marked in most cases of chronic lymphatic leukæmia, the splenomegaly is greatest in the chronic myelocytic type, where it may fill the abdomen and press upon the iliac crest and pubes. Local pain may be due to superadded thrombosis with infarction and perisplenitis. The liver commonly shows a similar firm enlargement.

The glandular enlargement, of greater degree in the chronic lymphatic type, has the suggestive feature of a more or less uniform involvement of all peripheral groups of glands, which are enlarged

symmetrically and to approximately the same degree. The glands are soft, discrete, painless and insensitive, and remain freely mobile. The discovery of a non-inflammatory swelling of isolated lymph glands in unusual situations, e.g. pre-auricular, subclavicular or intercostal, should raise suspicion of *chronic lymphatic leukæmia.* In *chronic myelocytic leukæmia* a diffuse enlargement of lymphatic glands also occurs, but is usually slight in degree and considerably less than in the lymphatic type. In both diseases deep groups of glands may show similar affection.

Leukæmia is to be regarded in nature as due to an excessive and unchecked proliferation of a particular variety of leucocyte or its precursor, the ætiology being quite obscure. The affected tissues all show histologically a stuffing of their tissue-spaces with these abnormal cells, replacing to a varying extent their normal structure, while the excess over and above their capacity of storage escapes into the circulating blood. This leukæmic infiltration may become evident in the skin as scattered discrete nodules, especially in the lymphatic form. Diarrhœa may be a feature and is then associated with similar infiltration of the intestine. A slow degeneration of health and secondary anæmia develop, with tendency to hæmorrhage and infection.

The diagnosis of chronic leukæmia and differentiation from other causes of multiple gland enlargement is established by blood examination. In both forms secondary anæmia is evident: in the case of chronic lymphatic leukæmia there is a great increase of total leucocytes, figures of 200,000 per c. mm. being common, of which the vast proportion, 95 per cent or more, are small lymphocytes; in chronic myelocytic leukæmia the total leucocyte count is even higher, perhaps double the figure mentioned, the predominant cells being the granular polymorphonuclears and their precursors in the bone-marrow, the myelocytes, neutrophil, eosinophil and basophil. These granular cells form the majority of the total white cells, although not usually present in such overwhelming proportion as are the lymphocytes in the lymphatic form.

In straightforward cases of chronic leukæmia the diagnosis will accordingly be made with certainty from a blood examination. Difficulty may sometimes arise in the rare forms of so-called "*aleukæmic leukæmia*," in which the general and glandular symptoms and signs are identical with those described, but no increase in the total leucocytes is found, sometimes indeed even a leucopenia. It is thought that the abnormal cells in this case remain confined in the lymphoid tissue and fail to escape into the general circulation. This condition does genuinely occur, usually as a temporary phase of an otherwise typical case of

leukæmia, but sometimes as a persistent state. The diagnosis is aided by a retention of the leukæmic proportions in the differential count, in spite of the total cell count not being raised. In a few cases it may be necessary to remove a gland for confirmatory biopsy, when typical replacement of its normal structure will be found by leucocyte infiltration of appropriate type.

In conclusion, and bearing in mind the difficulties so often met with in the individual clinical case in determining the exact pathology of glandular enlargement, the value of the microscope may perhaps be stressed as a final arbiter. Biopsy is indeed frequently the only means of converting conjecture into certainty.

CHAPTER IX

THYMUS

by

R. SLEIGH JOHNSON

THE thymus, albeit an organ of much dispute and conflicting views as to its essential nature and functions, is, as a study of its morphology shows, legitimately to be included in consideration of the lymphatic system.

Anatomy and Development. As the thymus is a temporary organ, reaching its maximum development during early childhood and thereafter normally undergoing a progressive absorption, its features are

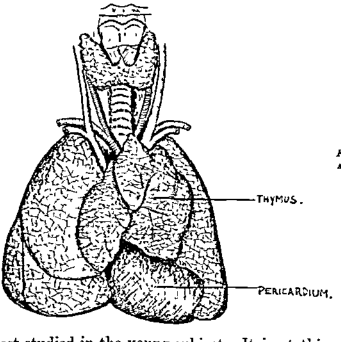

Fig. 2299 —THORACIC ORGANS OF A NEW-BORN CHILD, SHOWING THE RELATIONS OF THYMUS GLAND.

best studied in the young subject. It is at this age a soft, fusiform, lobulated structure composed of two lateral lobes, of which the left is usually the larger, situated behind the sternum and immediately in front of the pericardium, the origin of the great vessels and the trachea (fig. 2299). It frequently extends up into the root of the neck, as high in some cases as the isthmus of the thyroid gland. Laterally, it extends out to the pleural sac on each side, while below, its limit is usually

marked by the fourth costal cartilage, although when much enlarged it may reach down even to the diaphragm. A well-defined fibrous capsule surrounds the organ and sends septa inwards between its composing lobules. In actual size and weight great variation occurs, but an average is given of about 15 grammes at birth; proportionately to total body weight it normally reaches its greatest development between two and four years of age, although its maximum weight may not be reached until or just before puberty, when it is commonly between 35 and 40 grammes. Many factors are, however, concerned, including the relative proportions in the organ of fat or aveolar tissue and the more significant lymphoid tissue; the question is therefore further considered later.

Embryologically the thymus is developed from the endoderm of the third, and occasionally the fourth, branchial cleft, a pair of pouch-shaped diverticula arising from the dorsal aspect of the gill cleft and becoming steadily surrounded by lymphoid tissue. The lumen of these diverticula gradually becomes obliterated by thickening of their walls and an atrophy of their epithelial lining, which by the time of birth becomes represented merely by the concentric Hassall's corpuscles, in the substance of an otherwise solid lymphoid organ.

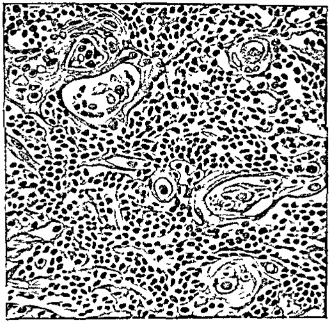

Fig. 2300.—Histological structure of the normal thymus at birth

Histology. The minute structure of the normal thymus is of special importance in view of the type and nature of pathological lesions which may develop. On histological section at the above age (fig. 2300) it is seen to be composed of a collection of lobules,

separated by fine connective-tissue septa. There is no clear subdivision of the lobule, as is sometimes described, into cortical and medullary areas, but each lobule contains a number of more or less discrete follicles of densely aggregated lymphocytes, similar to those of the tonsil or lymphatic gland, and more numerous in the outer zones of the lobule. Interspersed among these collections of lymphoid tissue, and relatively more numerous towards the centre of the lobule, are a number of characteristic nest-like bodies, the so-called Hassall's corpuscles. These show a concentric laminated arrangement of flattened epithelial cells around one or more central cells, the latter often degenerated, and represent the remains of a branching tube-like process of the original embryonic branchial cleft. The corpuscles are themselves surrounded by a rather coarser supporting reticulum than is found in the rest of the organ, thought also to be derived from branchial cleft epithelium. The cells of this reticulum are recognisable by their irregular outlines and large pale-staining nuclei. Eosinophil cells and giant cells are sometimes also found. As regards the bulk of the organ there is no reason to assume that the small, densely-staining round cells are other than true lymphocytes for eventual supply of the blood stream, although their nature has been disputed in favour of their being, like the reticulum cells, primarily epithelial in origin. Thus the thymus in the child consists mainly of an aggregation of lymphoid tissue, while undoubted epithelial elements are represented by Hassall's corpuscles and reticular tissue.

With the progress of atrophy towards adult life, the lymphoid tissue undergoes involution and gradually becomes replaced by fatty and areolar tissue, still containing scattered fragmentary deposits of lymphoid cells, interspersed to a varying degree of density with the epithelial Hassall's corpuscles. These latter tend thereby to become congregated and more prominent, and in some cases to appear more numerous. In others they share in the process of atrophy, until very little of the original glandular substance may remain demonstrable.

Physiology. Differences of opinion have formerly been held as to whether the thymus was to be ranked with the endocrine glands proper, or to be regarded as a specialised lymphatic structure. Although there is no convincing evidence of the production by the thymus of an internal secretion, all attempts to extract such a product having proved unsatisfactory, it is reasonably clear that an interrelation is present between the thymus and the known endocrine glands, in affections of a number of which the thymus becomes enlarged. The persistence of the organ until, and its progressive atrophy after, puberty, coincident with

functional development of the sexual organs and secondary sexual characteristics, is usually ascribed to a retarding influence of the thymus *on the evolution of sexual maturity, until such time as a suitable* degree of general growth and somatic development has been attained. The results of experimental removal in animals, although claimed by some observers to lend support to this theory by hastening sexual maturity, are, however, by no means uniformly in agreement. In view also of the not very infrequent persistence of histologically characteristic, and therefore presumably functioning, thymic tissue long after the changes of puberty or even into adult life, the question of its precise relationship, if any, to gonadic function must still be regarded as an open one.

The view now most widely held as to the probable physiological function of the thymus is to consider it a lymphoid organ belonging to the hæmatopoietic system, and to regard its epithelial elements as vestigial only and not as the source of an internal secretion. This conception finds confirmation in the part known to be taken by the thymus in some generalised affections of the lymphatic system.

PATHOLOGY OF THE THYMUS

Consideration of the pathology of the thymus may best be undertaken under the following headings:

1. *Hypoplasia.*
   (*a*) Normal (included for completeness); (*b*) premature.
2. *Hyperplasia.*
   (*a*) Apparently primary; (*b*) associated with other known diseases.
3. *Vascular Changes and Inflammations.*
   (*a*) Acute congestion and infection; (*b*) chronic infections; (*c*) involvement in inflammatory or hæmatogenous conditions of other systems.
4. *Tumours.*
   (*a*) Innocent; (*b*) malignant.

1. *Hypoplasia.*

(*a*) *Normal.* The *normal* process of involution of the thymus has been already discussed under physiology of the thymus.

(*b*) *Premature.* A pathological involution of the thymus, even a complete atrophy or aplasia of the gland, may be observed at an early age in a number of chronic infections and wasting conditions of childhood, such as infantile marasmus or tuberculosis, or in some cases from no apparent cause. In the former, it results probably from a long-

continued intoxication of the gland, the lymphoid tissue of which atrophies and is replaced by fibrous tissue, producing a densely sclerosed structure with scattered epithelial elements. With this marasmic atrophy of the thymus, other lymphoid tissues such as that of the spleen undergo a like change. No effect on sexual development is known to follow.

2. *Hyperplasia.*

(*a*) *Primary.* An apparently primary hyperplasia of the thymus, forming part of the clinical syndrome known as "*status thymo-lymphaticus*," is, in view of the importance and controversial nature of the subject, discussed separately under that heading (see page 4257).

(*b*) *Secondary.* A simple active proliferation of the thymus gland is known to occur in association with a number of glandular and other diseases. Of these the most important are *Graves' disease, Addison's disease, acromegaly*, and *myasthenia gravis.*

Enlargement of the thymus, sometimes gross, is found almost constantly post mortem in fatal cases of exophthalmic goitre, so much so that some pathologists of the French school formerly regarded the disease as due to a primary disturbance of the thymus, removal of which, rather than of the thyroid, was recommended. From the clinical standpoint, the thymus not infrequently shows sufficient enlargement to give impairment over the manubrium and to cast a characteristic shadow on X-ray examination, and sometimes to account for complaint of dyspnœa and mild dysphagia. The nature of the enlargement is a diffuse hyperplasia of lymphoid tissue, reflected in a moderate swelling of the cervical lymph glands and tonsils and a lymphocytosis in the blood picture. More strictly it may be described as a lymphocytic regeneration of a previously involuted organ, as Hassall's corpuscles are rarely present. The overgrowth is one which usually subsides after surgical treatment of the thyroid, and responds readily to the application of deep X-rays if this is required.

The hyperplasia seen in some cases of Addison's disease and acromegaly is of similar nature and is of no clinical importance. In myasthenia gravis the relationship is more significant, some abnormality of the thymus being found in a high proportion of cases. It may here be a simple hyperplasia, or a tumour such as a lympho-epithelioma of the thymus. The causal relationship, if any, is not understood. Removal of the enlarged thymus has been advocated in treatment.

3. *Vascular Changes and Inflammations.*

(*a*) *Acute congestion* of the thymus, sometimes with hæmorrhage into the gland, is found in a number of acute infections, especially in

broncho-pneumonia, and may be only an asphyxial phenomenon. Of surgical importance is the occasional acute congestion of the enlarged thymus following operations upon the thyroid in exophthalmic goitre, which may be productive of symptoms otherwise obscure.

Primary acute infection of the thymus has not been described, although the organ may become secondarily involved in any acute inflammatory condition of the mediastinum; suppuration may then occur.

(*b*) *Chronic infections.* Tuberculosis and syphilis of the thymus are both pathological rarities. The thymus may react to a number of chronic infections, either by hyperplasia of its lymphoid tissue or by atrophy and sclerosis. None of these conditions is of clinical importance.

(*c*) In diseases directly involving the lymphatic systems, such as leukæmia or lymphadenoma, the lymphoid tissue of the thymus may take part in the general response, in characteristic fashion with the remaining lymphoid structures of the body.

4. *Tumours of the Thymus.*

Primary tumours of the thymus are of less infrequent occurrence than would be inferred from customary accounts. If conditions of simple hyperplasia be excluded, innocent tumours are, however, rare and of little practical importance. The majority of thymic neoplasms show evidence of malignancy, varying from a low-grade local invasion to the most rapid and widespread metastasis.

Innocent tumours. Benign neoplasms include *lipomata, fibromata, dermoid cysts*, and *simple cysts* thought to originate from degenerated Hassall's corpuscles or from occasional inclusions of thyroid tissue. The term " thymoma " conveys no histological indication and its use is not therefore recommended.

Malignant tumours. The classification of primary malignant neoplasms arising in the thymus presents considerable difficulties, owing to lack of agreement on the part of various observers as to the histogenesis of the normal organ and the differences in nomenclature adopted.

The most useful classification would appear to be that put forward by Maximov in 1931, which is based upon the theory of development of the thymus outlined earlier in this section. The small rounded cells of the gland are regarded as derived from perivascular mesenchymal lymphocytes, which at an early stage wander into the primitive epithelium of the thymus. This cylindrical epithelium of entodermal origin becomes modified in character and converted into a reticulum-cell mass, and in the deeper portions of the gland into Hassall's corpuscles. The reticulum cells can be identified in a section by a special

method of staining which reveals fine argentophil fibres, for the most part concentrated around the blood-vessels.

On this histological basis of development, *malignant thymic tumours* may be classified as follows:

(1) Arising from the capsule and interlobular connective tissue—*spindle-celled sarcoma.*

(2) Arising from the reticulum cells and Hassall's corpuscles—*carcinoma.*

(3) Arising from the lymphocytes—*lymphosarcoma.*

Critical study of published cases by McDonald in the light of this classification has shown that a large proportion of thymic tumours

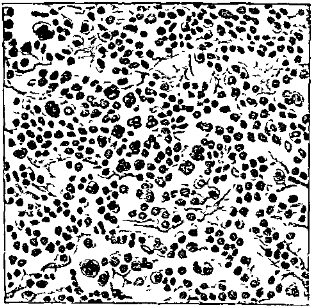

Fig. 2301.—PRIMARY RETICULUM-CELLED CARCINOMA OF THE THYMUS—HISTOLOGICAL STRUCTURE. (*Author's case.*)

previously interpreted as primary sarcomata have, in fact, a *common type cell* with strong morphological resemblance to the reticulum cell of the normal gland, and are most probably *reticulum-celled carcinomata* (fig. 2301). Confusion and difficulty arise from the markedly pleomorphic nature, both of these cells themselves and of their arrangement. The type cell is a large, irregularly rounded or polyhedral cell, which may be arranged in some cases in solid alveolar masses resembling a medullary adeno-carcinoma, in others in a stellate arrangement forming a loose anastomosing reticulum. Sometimes both types of formation are present in different areas of the same tumour, while giant cells, keratinised cells, or irregular calcified deposits may be evident. Again, transitions may be found to a flattened type of cell arranged in concentric whorls resembling the normal corpuscles.

It is thought that these variants arise from a primary proliferation respectively of the cells of Hassall's corpuscles and of the thymic reticulum, forming the common *alveolar* and *reticular type* of carcinoma. The striking histological feature of this variety of new growth is the extreme degree of variability. The type cell is sometimes spindle-shaped rather than rounded, although still a variant of the epithelial reticulum cell, while Hassall's corpuscles or their representations are by no means always to be found. The clue is, however, usually given by the discovery on search of at least some more fully differentiated types comparable with the normal cell.

Together with these epithelial constituents of the tumour are found aggregations of lymphocytes, again in a varying proportion. The admixture may be small, with preponderance of epithelial cells, or, on the contrary, lymphocytes may predominate, and epithelial elements be scanty. In the latter case they may sometimes be overlooked altogether, and an erroneous interpretation made of the tumour as being mainly sarcomatous. The lymphocytes tend, as in the normal organ, to show a perivascular distribution, and may be accompanied by plasma cells and eosinophil cells.

The predominance in some cases of lymphocytes has led to an alternative classification by Babes and by Matras and Prieskel in which these tumours are designated as *combined lympho-epithelial neoplasms* attempting to reproduce the entire structure of the thymus by the formation of reticulum cells and Hassall's corpuscles together with the lymphoid tissue. The variations in type are classified as under:

(1) *Pure epithelial tumours.*

(2) *Lympho-epithelial tumours.*

  (*a*) With *preponderance of epithelial type of cell* and admixture of lymphocytes in varying degree, these being limited to the perivascular region.

  (*b*) With *preponderance of lymphoid cells* and marked deficiency of epithelial elements. In this type the epithelial cells form part of the reticulum of the tumour, constituting a subdivision to which the term *lympho-reticular carcinoma* is sometimes applied.

Ewing holds the view that thymic carcinomata originate in connection with portions of involuted thymus, and that such tumours are frequently of the nature of infective granulomata, on the analogy of Hodgkin's disease, or of neoplasms consequent upon such granulomata. This latter view, however, has not received general support.

The symptoms of these malignant tumours of the thymus are usually local, and are confined to the pressure effects of the growth or its metastases, but Leyton, Turnbull and Bratton have described the occasional association of thymic carcinoma with pluriglandular disturbances, while Wu has noted the co-relation of lympho-epithelioma with myasthenia gravis.

No special description is called for of the histological features of truly sarcomatous and lympho-sarcomatous tumours arising in the thymus, these being identical with those found in other organs.

MACROSCOPIC AND CLINICAL FEATURES OF THYMIC CARCINOMATA

Although occurring at any age, these tumours are of most frequent incidence between the ages of 20 and 40 years, and are commoner in the male sex. The onset is usually gradual, with symptoms of unproductive cough and dyspnœa, from pressure upon the trachea, while, with extension of the growth, adjacent structures may similarly be obstructed or invaded. Cyanosis, with venous engorgement of the head and neck, may become marked from pressure upon the superior vena cava, with distension of surface veins and œdema of the chest wall or upper limbs. Stridor and pulmonary collapse may develop, and frequently a recurrent blood-stained effusion. In two of my own cases, the diagnosis was, however, obscured by the coincidence at onset of high intermittent fever with clear, sterile pleural effusion containing a predominance of lymphocytes, thought at first to be tuberculous, the true ætiology only being suspected later by persistent recurrence of fluid and heavy admixture of blood, increasing dyspnœa unrelieved by tapping, and development of œdema of one arm; post-mortem examination in each case revealed a large reticulum-celled carcinoma of the thymus with extensive metastases over pleura and diaphragm.

Pressure may occur upon nerves such as the phrenic, recurrent laryngeal or vagus, with hiccough and alterations of voice and of pulse-rate. Less often dysphagia results from posterior dislocation of the œsophagus. Pressure upon or direct invasion of the subjacent pericardium may give rise to excessive tachycardia from displacement or pericardial effusion.

The rapidity or otherwise, and the extent of development, of symptoms such as the above will vary greatly according to the degree of malignancy and rate of growth of the tumour, and in keeping also with its naked-eye features and tendency or otherwise to metastasise. In many cases growth is slow and only locally malignant. The tumour forms a firm, sometimes hard, mass filling the anterior mediastinum, and

is lobulated or nodular, with a varying attempt at encapsulation. On naked-eye section it is fleshy in appearance, and markedly vascular, often showing areas of hæmorrhage or of degeneration. The adjacent thymic tissue is compressed or replaced, and invasion may or may not have taken place through the fibrous capsule of the gland into adjacent structures. In some slow-growing tumours, the growth may long remain strictly localised to the thymus without spread to other structures. In other cases, with more rapid growth, the tumour is softer, perhaps friable and necrotic, greyish-red, shows no delimitation by a

Fig 2302.—PRIMARY CARCINOMA OF THYMUS, ILLUSTRATING MACROSCOPIC APPEARANCES. THE TUMOUR TISSUE HAS BEEN CUT AWAY FROM THE ANTERIOR ASPECT TO SHOW THE POSITION OF THE HEART, AND THE WIDESPREAD INFILTRATION OF THE PERICARDIUM, WITH EXTENSIVE SECONDARY DEPOSITS OVER THE PLEURA AND DIAPHRAGM. (*Author's case.*)

capsule, and may form a huge mass in the upper thorax and neck, infiltrating all adjacent structures and metastasising widely in lymphatic nodes and viscera. The lymph glands involved are usually the mediastinal, cervical and axillary; the visceral metastases are in most cases confined to the pleura, lung and diaphragm, but may invade the liver, kidney, spleen or distant organs as well as the long bones. The total duration of disease may be a matter of weeks, while the majority of cases prove fatal within a year, commonly from respiratory obstruction.

DIAGNOSIS OF THYMIC NEOPLASM

Clinical differentiation of tumours of the thymus from mediastinal neoplasms in general is in any case difficult, and for the most part

impossible. It is suspected from the symptoms already enumerated of pressure in the anterior mediastinum. Suspicion would be confirmed by localised dullness to percussion over the upper sternum, perhaps a visible local protrusion of the chest wall, marked venous distension, and suggestive appearance on X-ray examination.

Radiological investigation should be made in any case of suspected enlargement of the thymus from whatever cause. An opaque well-defined shadow in the anterior mediastinum, extending downwards and laterally and overlapping the heart shadow in front on each side, is suggestive of a thymic origin. Where the rare circumscribed tumour or cyst of the thymus is present, this may be evident from the definition or shape of the shadow.

General examination of the patient and special pathological investigations, such as biopsy of a lymph gland, a blood count or Wassermann reaction, will aid in excluding inflammatory conditions such as Hodgkin's disease or aneurysm.

Treatment. The majority of thymic tumours, from their position and malignant characteristics, are unfortunately not amenable to surgical removal. In these cases treatment will consist in symptomatic relief, where possible, of pressure effects, as from pleural effusion, together with deep X-ray or radium-bomb therapy to the affected area. Radiotherapy is usually only palliative in its effects, but appears to be temporarily most helpful in the group of sarcomata.

Where the evidence points towards a localised neoplasm of the thymus, attempt may be made, in some cases successfully, at surgical removal, either from above through the root of the neck or after longitudinal splitting of the sternum.

CHAPTER X

Status Thymo-Lymphaticus

by

R. Sleigh Johnson

In the consideration of thymic affections outlined in the preceding chapter, discussion was omitted of the syndrome reputed to result from simple hyperplasia of the organ and of other lymphoid tissues, to which has been given the name "status thymo-lymphaticus." Special consideration is merited in view of the controversy which still persists among many authorities even as to its claim to be regarded as a separate entity. Certainly the use of the term has been abused in its being made to cover up much pathological uncertainty and ignorance on the subject. A review of recent critical analyses and of the present state of knowledge, considered jointly with historical conceptions of the condition, may be helpful therefore towards an understanding of the problem.

Briefly, the syndrome, as described, relates in the main to the occurrence of sudden, dramatic death in apparently trivial circumstances. That this occurs not infrequently is beyond dispute and is a matter of general experience. A child, for example, previously considered fit, ceases breathing and abruptly dies for no obvious reason at the commencement of anæsthesia for a trivial condition, such as tooth extraction or, say, prior to tonsillectomy. A careful autopsy reveals no adequate explanation, the vital organs being to all appearances healthy; there may, however, in a proportion of cases be found unusual features of bodily structure and physique, together with apparent prominence of the thymus. The latter is seized upon as a suitable scapegoat and is made to explain an otherwise mysterious death, chiefly to satisfy legal demands. The difficulties in arriving at a truthful explanation are concerned not so much with the facts, which are not in dispute, as with their interpretation as to which are causal and which merely associated or incidental.

From the historical standpoint, much investigation was made to elucidate any factors in physique or build common to those who underwent sudden death in unexplained circumstances. Paltauf in 1889

was the first of modern investigators to implicate the thymus in its causation, although this had been noted in the literature as early as the beginning of the eighteenth century. While considering enlargement of this organ as the primary and invariable factor, however, he was careful to point out associated general changes, such as vascular hypoplasia, including that of the aorta, diffuse overgrowth of lymphoid structures, a fat flabby build and a tendency to feminism. To this combination of features he gave the name "status thymo-lymphaticus."

Symmers, at the Bellevue Hospital, New York, from a study of 4000 unselected post-mortem examinations, described the condition as follows: "A combination of hereditary constitutional anomalies, entering into which are certain peculiarities of configuration, with preservation or even hyperplasia of the thymus gland at an age when involution is to be expected, hyperplasia of the lymphoid cells in the lymph nodes, spleen, intestine and elsewhere; hypoplasia of the cardio-vascular system, developmental deficiencies in the genitalia, and, incidentally, visceral defects of uncertain occurrence and irregular distribution."

The overgrowth of lymphoid tissue was stated to be evident in the tonsils, tongue and naso-pharynx, in the cervical, axillary, mesenteric and inguinal glands, in Peyer's patches and in solitary follicles of the intestine and mucosa of the appendix. Enlargement of the spleen was found to be unusual, but lymphoid hyperplasia was present within the organ. Hyperplasia of the thymus he regarded as being constant, although in only half of his described cases was the weight of the organ recorded. The histological change common to all the enlarged organs was a marked, active proliferation of lymphocytes. Symmers described 6·2 per cent of his total of 4000 post-mortem cases as belonging to this type, in which males predominated by six to one.

Hyperplasia of the thymus, before full description of this syndrome, had long been held to account not only for sudden and unexplained death, but also for disturbances in childhood of lesser severity, characterised chiefly by dyspnœa and originally graded by Warthin as "thymic stridor" and "thymic asthma" respectively. The former, as described, consists of attacks of stridor in the first few months of life, coming on especially after a screaming fit or throwing back of the head, severe bouts being accompanied by signs of respiratory obstruction such as intercostal recession. "Thymic asthma," so-called, is but a further degree of paroxysmal dyspnœa of inspiratory type, with cyanosis or greyish pallor of the face, distended cervical veins, and intense overaction of accessory muscles. Unless relieved, collapse is

liable to follow, with flaccidity, dilated pupils, feeble heart sounds, and death. In both groups, symptoms were ascribed to mechanical pressure upon the trachea by enlargement of the thymus, although such stenosis could by no means frequently be demonstrated post mortem.

The work of Paltauf and Symmers stimulated interest, and many further cases were put on record of sudden death with reputed thymic enlargement, so that for a number of years this easy though inadequate explanation received tacit acceptance. Subsequent analysis of these and similar publications, however, showed that observations made therein upon the thymus assumed to be pathologically enlarged were based on widely varying standards of normality as regards size and weight of the thymus in health at different ages and periods of growth. Hammar in 1926, in an exhaustive study, first put these standards upon an established basis, indicating the variations in the weight of the organ which must be accepted as within the physiological range in relation to age, sex, height, body weight and weight of other organs. Although rough approximations were found between which the majority of normal figures lay, nevertheless wide limits, up to some hundreds per cent, were found occasionally to be compatible with normal health and unassociated with symptoms of the "thymic syndrome."

When put to the statistical test, the case for hyperplasia of the thymus *per se* being responsible for sudden death was found to break down. Some further and wider explanation had to be sought for. Observations were continued by Greenwood and Woods, and jointly with them by Professor Turnbull, to discover, by analysis of a very large series of post-mortem examinations on young subjects, whether these high deviations from the average figure for weight of the thymus occurred any more frequently in cases of reputed "thymic death" than in death from any other unselected cause, as, for example, from accident. Their conclusions, though largely negative, nevertheless threw some light on the question. Taking the weight of the organ alone, although they found no general tendency to an increase in size, that is, to hyperplasia, of the thymus in the former group, they were able to demonstrate a greater degree of variability in weight around the mean figure in those cases where sudden death had occurred than in the control group. The probability of the organ being either larger or smaller than the average for that age was greater in the former group than in cases of death from other causes. Their conclusion on the theory of hyperplasia was that the terms "status lymphaticus" and "status thymo-lymphaticus" were "mere verbalisms."

was the first of modern investigators to implicate the thymus in its causation, although this had been noted in the literature as early as the beginning of the eighteenth century. While considering enlargement of this organ as the primary and invariable factor, however, he was careful to point out associated general changes, such as vascular hypoplasia, including that of the aorta, diffuse overgrowth of lymphoid structures, a fat flabby build and a tendency to feminism. To this combination of features he gave the name "status thymo-lymphaticus."

Symmers, at the Bellevue Hospital, New York, from a study of 4000 unselected post-mortem examinations, described the condition as follows: "A combination of hereditary constitutional anomalies, entering into which are certain peculiarities of configuration, with preservation or even hyperplasia of the thymus gland at an age when involution is to be expected, hyperplasia of the lymphoid cells in the lymph nodes, spleen, intestine and elsewhere; hypoplasia of the cardiovascular system, developmental deficiencies in the genitalia, and, incidentally, visceral defects of uncertain occurrence and irregular distribution."

The overgrowth of lymphoid tissue was stated to be evident in the tonsils, tongue and naso-pharynx, in the cervical, axillary, mesenteric and inguinal glands, in Peyer's patches and in solitary follicles of the intestine and mucosa of the appendix. Enlargement of the spleen was found to be unusual, but lymphoid hyperplasia was present within the organ. Hyperplasia of the thymus he regarded as being constant, although in only half of his described cases was the weight of the organ recorded. The histological change common to all the enlarged organs was a marked, active proliferation of lymphocytes. Symmers described 6·2 per cent of his total of 4000 post-mortem cases as belonging to this type, in which males predominated by six to one.

Hyperplasia of the thymus, before full description of this syndrome, had long been held to account not only for sudden and unexplained death, but also for disturbances in childhood of lesser severity, characterised chiefly by dyspnœa and originally graded by Warthin as "thymic stridor" and "thymic asthma" respectively. The former, as described, consists of attacks of stridor in the first few months of life, coming on especially after a screaming fit or throwing back of the head, severe bouts being accompanied by signs of respiratory obstruction such as intercostal recession. "Thymic asthma," so-called, is but a further degree of paroxysmal dyspnœa of inspiratory type, with cyanosis or greyish pallor of the face, distended cervical veins, and intense overaction of accessory muscles. Unless relieved, collapse is

liable to follow, with flaccidity, dilated pupils, feeble heart sounds, and death. In both groups, symptoms were ascribed to mechanical pressure upon the trachea by enlargement of the thymus, although such stenosis could by no means frequently be demonstrated post mortem.

The work of Paltauf and Symmers stimulated interest, and many further cases were put on record of sudden death with reputed thymic enlargement, so that for a number of years this easy though inadequate explanation received tacit acceptance. Subsequent analysis of these and similar publications, however, showed that observations made therein upon the thymus assumed to be pathologically enlarged were based on widely varying standards of normality as regards size and weight of the thymus in health at different ages and periods of growth. Hammar in 1926, in an exhaustive study, first put these standards upon an established basis, indicating the variations in the weight of the organ which must be accepted as within the physiological range in relation to age, sex, height, body weight and weight of other organs. Although rough approximations were found between which the majority of normal figures lay, nevertheless wide limits, up to some hundreds per cent, were found occasionally to be compatible with normal health and unassociated with symptoms of the "thymic syndrome."

When put to the statistical test, the case for hyperplasia of the thymus *per se* being responsible for sudden death was found to break down. Some further and wider explanation had to be sought for. Observations were continued by Greenwood and Woods, and jointly with them by Professor Turnbull, to discover, by analysis of a very large series of post-mortem examinations on young subjects, whether these high deviations from the average figure for weight of the thymus occurred any more frequently in cases of reputed "thymic death" than in death from any other unselected cause, as, for example, from accident. Their conclusions, though largely negative, nevertheless threw some light on the question. Taking the weight of the organ alone, although they found no general tendency to an increase in size, that is, to hyperplasia, of the thymus in the former group, they were able to demonstrate a greater degree of variability in weight around the mean figure in those cases where sudden death had occurred than in the control group. The probability of the organ being either larger or smaller than the average for that age was greater in the former group than in cases of death from other causes. Their conclusion on the theory of hyperplasia was that the terms "status lymphaticus" and "status thymo-lymphaticus" were "mere verbalisms."

In view of the importance of these observations, in 1926 a joint committee of the Medical Research Council and the Pathological Society of Great Britain and Ireland was established to investigate the problem still more closely. Their broad conclusions confirmed the opinions of the previously named observers in finding no evidence that the so-called "status thymo-lymphaticus" existed as a pathological entity.

The problem thus became increasingly complex and still unsolved. No positive evidence having been deduced regarding a constant abnormality in size or weight of the thymus, attention was directed to possible significant factors in the minute structure of the gland, a direction of study included by Hammar in his analyses. He investigated the organ from the aspect of the degree of proliferative or involutional changes present, taking as indices the relative proportions to one another in the gland of Hassall's corpuscles of differing sizes. These "Hassall's ratios" were obtained by classifying the corpuscles into three groups according to diameter. With this as criterion of internal structure, analysis by Greenwood has shown an interesting analogy with his observations on total weight. While no significant difference is found in the average figure of the two groups as regards the size of Hassall's corpuscles, nevertheless a greater degree of variability around the mean figure could again be demonstrated, taking the group as a whole rather than individual cases.

To summarise, the evidence regarding the thymus in these states which is justified by critical analysis indicates, therefore, a degree of instability of the organ in weight and structure, to be interpreted with most probability not as causative, but merely as part of a generally greater instability of the body as a whole.

With the disproving of a primary part played by an enlarged thymus, the theory of a fatal result being brought about by pressure on the trachea or vagus has to be abandoned. Death, moreover, in these cases is too sudden to be due entirely to asphyxia. A theory which appears more reasonable is that death occurs from a form of *anaphylactic shock* with sudden vagotonia and cardiac inhibition.

This theory has been studied fully by Symmers among others, taking a wider view of the syndrome and anatomical changes. He described two anatomical types: firstly, a condition of "*status lymphaticus*," with well-marked lymphoid hyperplasia throughout the body, including often a lymphocytosis in the blood and an accompanying susceptibility to anaphylaxis, urticaria, asthma, convulsions, and (rarely) sudden death, together with a lowered threshold to infection

and defective development of the muscular coats of the arteries; and, secondly, a condition of "*recessive status lymphaticus*," in which bodily configuration remains unchanged, but involutional atrophic changes have occurred throughout the lymphoid tissues. In this second group, as the lymphoid structures undergo involution so the tendency to anaphylaxis diminishes and with it the danger of sudden death. The first group predominates in childhood and tends with adolescence to pass into the second.

The theory is supported by the microscopic changes he describes in the lymphoid tissues in cases where sudden unexplained death has occurred. In such cases he has found abundant areas of necrosis in the germinal follicles of the lymphoid tissues throughout the body. These are present in all stages both of the necrotic and of the reparative phases, the former predominating. His theory is that the hyperplastic lymphoid tissue, especially in the naturally exposed situations of the upper respiratory and gastro-intestinal tracts, is subjected to repeated minor chemical and toxic trauma, to which it reacts by focal necrosis; that in this process a specific nucleo-protein is liberated to which the lymphoid tissues become sensitised. Subsequent exposure to the stimulus produces further necrosis and liberation of toxin, with an anaphylactic reaction varying according to the intensity of stimulus, which reaction, if marked, is shown by sudden death.

Such a theory, though admittedly hypothetical, at any rate goes further to explain the known facts than any other so far put forward, and links together the minor and major manifestations into a single conception.

It remains to refer to the operative risk and to discuss what prophylactic measures, if any, are to be adopted where the need for caution is suspected from the clinical type. In a fat, flabby male child with palpable glands and enlarged tonsils, especially if a blond, operation should be undertaken only if really necessary, and any catarrhal infection of the upper respiratory tract first treated with thoroughness. Emotional excitement, excessively strenuous exercise, and extremes of temperature in bathing should be avoided, and any evidence of rickets given appropriate treatment. If radiological examination shows a large thymic shadow, cautious X-ray treatment to the gland region is indicated prior to operation. Some estimation of the need for caution is to be obtained from a differential blood count, the danger of anaphylaxis being the greater in proportion to the percentage of lymphocytes present, since the latter may be accepted as a more or less reliable index of the degree of general lymphoid hyperplasia in the body.

CHAPTER IV

Fractures

In conjunction with H. L.-C. WOOD

ORTHOPÆDICS

Introduction

In Volume II of this work (Part XVI), under the comprehensive title of "Orthopædics," the following subjects were discussed: Deformities of the Feet; Disabilities of the Knee Joint; Acute Osteomyelitis; Acute Arthritis; Open or Compound Fractures; Muscle and Tendon Injuries; and The Surgery of the Peripheral Nerves.

This part is a continuation of the subject, and I have here described in some detail: Operations upon the Joints; Tumours of Bone (with special reference to Sarcoma); and those aspects of Fractures not dealt with in Volume II. The value of certain operations for Tuberculosis of the Joints is described, but no attempt has been made to discuss the routine treatment of any one joint affected with this disease. A detailed account of Amputations and the Operative Procedures upon Joints is given, the former because it is important and the latter on account of the definite advances that have been made in this branch of surgery during the past twenty years.

In subsequent editions of this work the whole subject of Orthopædics will be incorporated in one single volume.

CHAPTER I

Amputations

The term *amputation* is employed when an operation is performed to remove a portion of a limb by dividing the bone, whereas *disarticulation* indicates division through a joint.

Injury and disease of a limb are clearly the causes for which amputation is required, and there is no intention of discussing in any detail the indications for each operation. However, it is most important for the surgeon to appreciate that, in deciding the level of amputation, he should consider not only the damaged or diseased portion of the limb, but also the production of a stump which will be able to fulfil a useful function. When amputation is carried out as a life-saving measure, or near an infected area, it may not be possible to give as much consideration to the stump as in a "set operation." At times, amputations will be carried out as a preliminary operation, with the realisation that when life has been saved and infection is absent, a set operation may be necessary to make a satisfactory stump. However, if the emergency operation is carried out with thought as to the level of bone division, and skill with regard to the division of skin and muscle, the second amputation will often not be required.

A knowledge of artificial limbs will assist in deciding which will be the most satisfactory stumps produced by the various types of amputation and disarticulation.

AMPUTATION STUMPS

In *both upper and lower limbs*, it is advisable for:

(1) The skin over the end of the stump to fit neatly without undue tension; (2) the scar to be painless and placed so that it does not become rubbed or pressed upon by the artificial limb; (3) the shape to be regular with no irregular bulges at the end of the stump; (4) the end of the bone to be well covered by soft tissues; (5) the whole stump to be painless; (6) the divided nerves to be painless; and (7) the joint above the stump to be painless and have a full range of movement.

In the *lower limb*, the stump either has to bear weight directly—end-bearing—as in Syme's amputation, or it is used as a lever when

weight-bearing is taken by bony prominences above the stump. This is exemplified by: (*a*) Mid-leg amputation, when the bucket of the artificial limb fits against the head of the tibia and the lower border of the patella, and the leg stump is the lever; and (*b*) supracondylar amputation, when weight-bearing is taken by the tuber ischii, and the thigh stump acts as a lever (fig. 2303).

Sacrifice of some length of limb is often advisable in order to produce

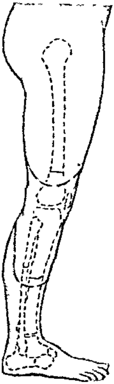

Fig 2303.—Diagram showing the two best amputations of the lower limb. The shape of the stump and the line of bone section are indicated in each case.

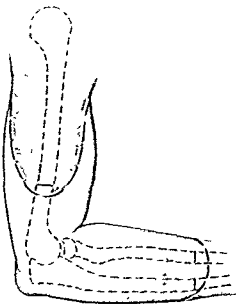

Fig 2304.—Diagram showing the two best amputations of the upper limb. The shape of the stump and the line of bone section are indicated in each case.

a stump satisfactory for weight-bearing and thus for function. A scar at the end of the stump or an adherent scar is undesirable.

In the *upper limb*, weight-bearing is not required, and the function of the stump is limited to the transmission of movement, so that objects can be moved and held.

Every effort should be made to provide as long a stump as possible, but the situation of the scar is of little importance provided the flaps are cut so that the scar has a good circulation and does not tend to ulcerate (fig. 2304).

Particular attention to the technique of dealing with the nerves is of paramount importance.

TECHNIQUE OF AMPUTATION

A *tourniquet* is used as a routine measure, and is placed as far above the site of operation as possible. It is contra-indicated when the blood-vessels are calcified, and cannot be employed in amputations and disarticulations about the shoulder and hip joints.

Skin flaps. The total length of the flap or flaps should be that of the diameter of the limb at the level of bone section. Sometimes a shorter length is sufficient, as in the thigh where skin stretches readily. The old rule of " a diameter and a half " produces a loose flap, and was formulated when retraction of skin followed granulation of the wound. The type of flaps cut differs in various countries and also amongst surgeons in this country. It is advisable to be conversant with the recognised methods of cutting flaps, for each type is useful in some portion of a limb.

The *circular* skin flap is suitable for portions of a limb that are more or less cylindrical. It is usually modified by two lateral vertical incisions, which really convert it into two equal flaps.

The *elliptical* skin flap is little used in this country, but is suitable for portions of a limb that are conical. This may be converted into a *racket incision* by adding a vertical incision from the highest point of the ellipse.

The *flap method* means the cutting of two rectangular or semi-circular incisions (either equal, or with one flap larger than the other) or of a U-shaped flap of skin from one surface. These flaps should be from the flexor and extensor surfaces (i.e. anterior and posterior) rather than lateral flaps. As a rule, the longer flap should be cut from the extensor surface. The subcutaneous tissue should be included in the skin flap and not separated from the skin. If there is an excessive amount of fat, it is advisable to remove some of the deeper portion of this.

Muscle and muscle sheath. As a general rule, these should be divided at right angles to the long axis of the limb and below the line of bone section. Tendons should be divided at a similar level and not withdrawn from their sheaths. It is advisable to allow sufficient muscle to cover the end of the bone and make a regular-shaped stump. If too much muscle is left the stump is unnecessarily bulky. In certain amputations, such as those directly above the knee joint, a good covering for the bone is obtainable by including the muscular and aponeurotic tissue in the skin flap, but this is not desirable as a general principle. The attachment of tendons to the flap or scar is undesirable.

Bone and periosteum. Muscles should be retracted by an assistant holding an efficient muscle retractor or device which enables the operator to see the bone clearly and prevents muscle tissue from coming

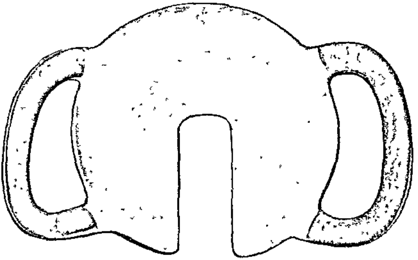

Fig 2305—MUSCLE RETRACTOR SUITABLE FOR USE IN AMPUTATION OF THE THIGH.

in contact with the saw (fig. 2305). The periosteum is divided with a knife just above the proposed line of bone section and is gently pushed upwards (fig. 2306). The lower cuff is pushed downwards, and the bone sawn through at right angles to its long axis. If any prominence remains owing to the bone being irregular in shape (e.g. the tibia), this prominence is rounded off, or it can be sawn partly through before the bone is divided. If this method of dealing with periosteum and bone is followed in clean amputations, the end of the bone will round off and the end of the medullary cavity become covered with compact bone. If the end of the bone is covered with periosteum or a flap of bone covered by periosteum (osteoplastic), there is a likelihood of the end of the bone becoming thickened and of spur formation taking place.

Fig. 2306. — THIS PICTURE INDICATES THE RESULT OF REFLECTING THE PERIOSTEAL FLAP; THE APPROPRIATE LINE OF BONE SECTION IS SHOWN.

Hæmorrhage. The main blood-vessels are divided transversely and neatly, and are picked up singly with artery forceps. Others visible are dealt with similarly, and each is ligated in turn with catgut. Non-absorbable material tends to form a nodular scar and, in the presence of sepsis, acts as a foreign body. When all visible vessels have been ligated, the tourniquet is removed and other vessels are picked up and tied. A basin of sterile saline at 120° F. is then placed beneath the stump and the wound bathed. This will arrest oozing and make

a number of smaller vessels more visible. When it is realised that the *main vessels* are *calcified* it is unwise to use a tourniquet, as this may injure the artery and therefore damage the blood supply to the peripheral part of the stump. As digital compression may have a similar detrimental effect, it is advisable to proceed deliberately by picking up the vessels bleeding after division of the skin, and then to cut down to the main vessels and pick them up with artery forceps before division. Other large vessels can be dealt with similarly. In particular amputations, such as disarticulation at the hip or shoulder, a tourniquet cannot be used and it is expedient to cut down on to the main vessels and ligate them above and below the place where they are to be divided, before proceeding further with the amputation.

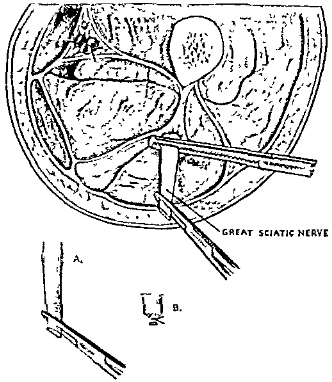

Fig 2307.—Diagram showing method of division of a nerve in an amputation. The great sciatic nerve is pulled down and clamped.

A. Shows effect of clamp on nerve.

B. Shows ligation through area clamped.

Nerves. When the blood-vessels have been ligated, each nerve in turn is pulled down by traction with forceps. A strong pair of artery forceps is then placed at right angles to the nerve and as high up as possible. The nerve is well crushed and a catgut ligature placed round the nerve at the crushed point. The nerve is then divided just below the ligature (fig. 2307). The object of this is to confine to the inside of the sheath new axis cylinders which form, thereby limiting the size of the pseudo-neuroma and adherence to surrounding structures.

The injection of formalin, alcohol, novocaine, or other fluids is not advocated.

Closure of the wound. Muscles and their sheaths are stitched together over the end of the bone to cover the divided area, obliterate dead spaces, and give the desired shape to the stump. A rubber drainage-tube with a safety-pin through one end is inserted with one or both ends protruding at the lateral edges of the scar. The skin and subcutaneous tissue are sutured accurately with a number of strong interrupted sutures, and then with a fine continuous stitch. The stump is covered with a large dressing of gauze and wool and firmly bandaged with a 6-inch gauze roll, after which another layer of wool is bandaged on. A piece of elastoplast is then placed in the long axis of the limb to prevent the tendency of the dressing to come off the end of the stump. The stump is then placed on a small pillow. In lower limb amputation a thin towel is spread over the stump and pillow and fixed by sand-bags.

After-Treatment. The drainage-tube is removed in forty-eight hours. This can often be accomplished without removal of the whole dressing, which saves the patient both pain and anxiety. After this the stump is left free on the pillow. The skin sutures are removed in ten days and the patient is encouraged to move the stump. He gets out of bed when the sutures are out in the case of upper limb amputations, and after three weeks in lower limb amputations. The stump is kept firmly bandaged, but movement is encouraged, so that it does not become flexed at the joint proximal to the amputation. This is particularly important in thigh amputations.

Kineplastic amputation. Attempts have been made in upper limb amputations to adapt the ends of the bones, muscles and tendons so that they have direct control over mechanical contrivances, without the use of an artificial limb. The lower end of the forearm has been the area of choice for this type of operation, but ingenious as have been the operative procedures, the function produced has been in most cases useless.

AFTER-TREATMENT OF AMPUTATIONS

A week after the wound is healed the stump should be washed with soap and water, dried, dehydrated with spirit, and powdered. It should be massaged daily, and the patient encouraged to move the proximal joints. A firm bandage will be comfortable, preserve the shape, and help the shrinkage.

In the case of the lower limb, it is most important to get the patient out of bed, both using crutches and wearing a pylon as soon as possible. This is to prevent flexion deformity of the knee in below-knee amputations and flexion-adduction deformity in thigh amputations.

A pylon consists of a bucket made of plaster from a cast and lined with felt at pressure points. The bucket is fixed to hickory sticks as is shown in figure 2308.

This apparatus enables the patient to learn to balance, usually using one crutch, and keeps the stump mobile. As the stump shrinks, a new bucket can be made, and when the stump has reached a stable condition a permanent artificial limb

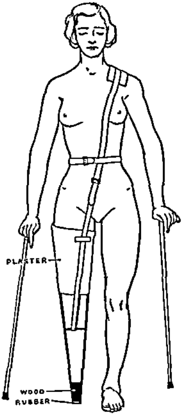

Fig. 2308.—Patient walking with a pylon suitable for a case of thigh amputation. The bucket is of plaster lined with felt. The uprights are of hickory. A webbing strap passes over the shoulder of the opposite side, which is protected by a felt pad. The patient uses two sticks.

is provided. The patient learns how to use the more complicated apparatus with far less difficulty after six months' use of a pylon.

Skin irritation or infection of a stump always requires attention, and the artificial limb should not be worn until it is relieved.

COMPLICATIONS IN AMPUTATION STUMPS

Conical stump. This arises: (1) in childhood from growth of the bone within the stump, or (2) from retraction of muscles cut too short at the time of primary amputation.

(1) This complication cannot be prevented. Owing to the situation of the "growing end" of the bone, it is seen most frequently after *amputation through the arm or leg in children. An early re-amputation* will be followed by a further conical stump, unless a long piece of bone is removed and very amply covered by soft tissues. Unfortunately, if the conical stump is left indefinitely, the tissues over the end of the bone gradually become thinned until ulceration of the skin may occur. It is advisable to delay the re-amputation as long as possible, and if it

has to be done before the age of sixteen ample covering must be placed over the end of the bone. Any operative procedure on the metaphysis, where the new bone formation is occurring, which aims at stopping this growth is to be condemned in the case of the conical stump, as it is impossible to ensure cessation of growth in a regular manner. It is inadvisable to operate on the base of a stump, where pressure often occurs from the artificial appliance, and the risk of producing deformity there is greater than is the chance of an eventual good stump by the method already suggested.

(2) A conical stump in an adult necessitates re-amputation if the artificial appliance is not working efficiently or if there is pain or a tendency to ulceration over the end of the stump. It is advisable to operate at a time when there is no granulating area over the end of the bone, and the operation is carried out on the lines of an amputation at a higher level.

Scar tissue. If there is a painful scar, particularly at a pressure area of the artificial limb, this should be excised. Often there is thickened rough skin and alteration in the vascularity around such a scar. The artificial limb should not be worn for three weeks or so prior to operation, and the skin should be cleansed and softened. If possible, a wide area of skin including the scar should be removed and the suture carried out accurately. Advantage is often gained by closing the wound in such a way that the new scar lies in a different position from that of the old painful area.

Painful neurofibroma. This arises from imperfect technique in dealing with a nerve at the primary amputation, and often after amputations carried out through infected areas. The nerve bulb and 1 inch of nerve above should be exposed through an incision in a line with the nerve. The nerve proximal to the bulb is freed and traced down to the bulb, which is dissected from the surrounding fibrous tissue (see fig. 2309). This is then grasped firmly with strong hæmostats and the nerve pulled down. The nerve is then crushed and tied off, as described under Technique in dealing with nerves. It should be possible to crush it 2–3 inches above the bulb. Experience after the War showed that the new nerve bulb formed was sometimes painful, even when the secondary operation was carried out with due care. It is suggested that this was due to a chronic inflammatory condition present in the nerve, and that the tendency was for the bulb to get less tender after some months, whereas injections of alcohol or other fluid were inclined to irritate the nerve structure and increase the symptoms.

Spurs. Spur formation may occur at the end of the bone. A spur

results from ossification in muscular or tendinous tissue attached to the edge of the end of the bone. The rough stripping up of periosteum, particularly in the presence of mild infection, may be the primary cause. A spur can often be prevented by cutting away the periosteum proximal to the line of bone section, and by dividing the muscular attachment to the bone for an inch above the end of the stump (e.g. muscular attachment to linea aspera in thigh amputations).

The existence of a spur, found on palpation in a stump not well covered, or seen in a skiagram, does not call for treatment unless it is

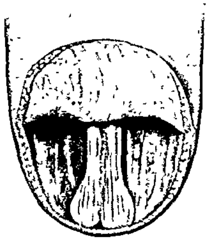

Fig. 2309.—An amputation stump with a flap turned up to expose two neuro fibromata, adherent to one another and to the subcutaneous tissue and skin. (*Museum, King's College Hospital*).

Fig. 2310.—The distal three inches of the femur removed from a septic amputation stump in which a sinus existed. A sequestrum is shown in a cavity in the bone. There are cloacæ, such as are found in chronic osteomyelitis.

painful. In removing a spur care must be taken to avoid rough treatment of the bone, periosteum and muscular attachments, or else another spur may form; when a number of spurs are present round the end of the bone, it may be advisable to remove the distal $\frac{1}{2}$-inch of the amputated bone with the spurs attached.

Sinus in a stump. A persistent sinus indicates infection around a foreign body, which is usually a piece of non-absorbable ligature or a sequestrum, or, rarely, is due to a retained drainage-tube. Apart from faulty technique at the primary operation, this occurs when the amputation has been carried out for an infected condition of the extremity. The primary wound may not have healed in its entire length, and a small discharge occurs at one corner, particularly at the angle through which the drainage-tube emerged. If silk or thread has been used for ligature

of the vessels, it is best to wait in the hope that the ligature will discharge itself. If after two months the sinus is unhealed, a skiagram should be taken of the stump. A sequestrum is likely to be a small piece of bone, or a complete ring with spikes of bone proximally, which is separating from the shaft. A sequestrum should be removed as soon as the X-ray appearance suggests that it is free from the shaft. It is preferable to avoid cutting bone away, as further infection may occur (fig. 2310). It is inadvisable to close the wound completely, and it should be cleansed with spirit, packed with flavine and paraffin, and dressed weekly. If there is *osteomyelitis of the shaft* for some distance up the bone, re-amputation may be advisable above the infected area; this usually means above the proximal joint. In the case of the femur every effort should be made to preserve this, and an operation carried out on the lines of one for chronic osteomyelitis through an incision on the lateral aspect of the limb may be required and prove satisfactory.

A *granulating stump* is considered subsequently (see page 4277).

AMPUTATION IN THE PRESENCE OF SEPSIS

This is usually performed as a life-saving measure, when the surgeon's primary thought is the patient's life, with the realisation that a perfect stump may not be obtained from the primary amputation. It is practised most frequently in cases of infection superimposed on moist gangrene of the foot, gas gangrene, gunshot wounds, and severe infection of the tendon sheaths of the palm.

It must be realised that the tissues at any level of the limb are likely to be infected, although this may be indicated only by œdema, particularly around the vessels and in the subcutaneous tissue. Amputations through large joints should be avoided; Syme's amputation and those through the tarsus and metatarsus should not be carried out in the presence of sepsis.

As a life-saving measure the most simple operation to perform through the thigh or arm is that popularly called the "*guillotine*" *amputation* (see fig. 2311). A tourniquet is used, and the skin, muscle, and bone are divided in turn at the same level. The blood-vessels and nerves are dealt with as in any amputation. The large open wound is covered with a dressing soaked in flavine-paraffin emulsion.

This method can be modified by the use of *flaps*, and such is the operation of choice. The flaps should be cut so that the extensor surface flap is twice as long as that from the flexor surface. The muscles are divided and, without unduly disturbing them after division, the bone is divided about 1 inch above the level to which they retract. The vessels

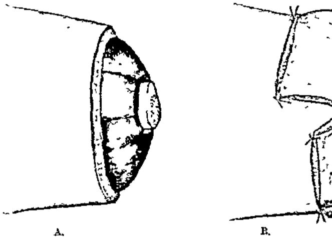

Fig 2311.—A. Appearance of stump after "guillotine" amputation. B. Appearance of stump after modified "guillotine" amputation with flaps stitched back.

and nerves are dealt with, and the skin flaps are sutured back to the skin above by a stitch at each corner. This leaves the muscles and possibly bone exposed. A flavine-paraffin dressing is placed over the exposed area. After seventy-two hours, if the patient's condition is satisfactory and the stump looks clean, the stitches are cut and the skin flaps are allowed to fall over the granulating muscle, but are not stitched. They will often cover it completely, as œdema of the muscle and subcutaneous tissue will have subsided.

If infection is present, the skin flaps are not unstitched for a week or so. After this time, whether the stump is clean or not, it is unlikely that they will cover the stump, but the dressings will be less painful and the healing time shorter than with the "guillotine" method.

Should it appear that the stump is unlikely to become a serviceable one when the patient's general condition has improved, two lines of treatment are possible:

(1) To apply extensions of strapping to the skin of the stump in order to draw this down. The other end of the extensions can be applied

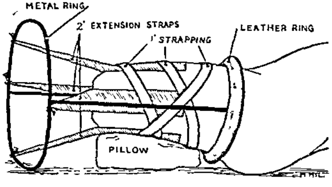

Fig. 2312.—Apparatus used to apply extension to skin in cases of skin retraction after amputation, such as may follow the "guillotine" operation.

to a ring as in figure 2312. This is always necessary in the "guillotine" operation; or

(2) To re-amputate the granulating stump. It is advisable to allow it to granulate until the unhealed area is the size of a large watch. If sequestration of the end of the bone occurs, this should be dealt with prior to the re-amputation. *As a preparation for secondary operation*, the area should be thoroughly cleansed, all scabs removed, and the surface painted with iodine twice a day for three successive days. Re-amputation must be carried out as far from the granulating area as the length of stump permits, and the technique must be planned so that the granulating area is not touched by instruments in the course of operation.

CONTRACTURES AND VASOMOTOR DISTURBANCES

It is recognised that subsequent to amputation a number of patients get a painful stump with contracture of the proximal joint. Often the *stump is cyanosed in colour and tender to touch, and the patient keeps* it wrapped up in layers of wool and bandages. Such a stump is seen at times when amputation is carried out for causalgia, and at other times for no reason which can be ascertained; the condition is most distressing to the patient, and the surgeon often proceeds from one operation to another without producing any relief. The primary treatment of causalgia is one of great difficulty, and in the other group of cases our knowledge of the ætiology is so deficient that no one can foretell whether any measure will produce relief. The efforts at relief that have been carried out include nerve injection, operations on the sympathetic nervous system and spinal cord, and re-amputation. The last is often *followed by removal of a further portion of the limb.*

The Lower Extremity

AMPUTATIONS OF THE TOES

(1) The *terminal phalanx* is amputated in cases of deformity of a toe with a painful corn or nail. A plantar flap is used with a transverse dorsal incision directly above the nail. The plantar flap is dissected back, and after the terminal phalanx has been removed the flaps are sutured in position.

(2) *Partial amputation of toes* through phalanges or the proximal interphalangeal joint is undesirable.

(3) *Amputation of an entire toe*, i.e. through the metatarso-phalangeal joint, is often required. The racket incision, that is, using lateral flaps, is the most satisfactory. In the 2nd, 3rd and 4th toes, the handle of the

racket lies in the middle of the dorsum of the toe, the uppermost point being above the metatarso-phalangeal joint. The flaps pass round the toe just distal to the web (fig. 2313). The incision is carried down to the bone; the two dorsal and plantar arteries are secured in the flaps; the plantar ligament is divided against the base of the first phalanx; the phalanx is enucleated; and soft structures not already divided are cut through. The incision for amputation of the 5th toe is indicated in the diagram. Amputation of the 4th and 5th toes leaves a strong foot, but amputation of the 2nd and 3rd toes is followed by hallux valgus and is often unsatisfactory. When any three toes have to be

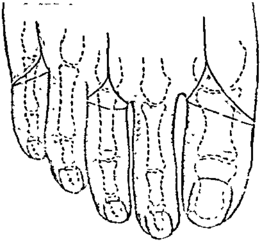

Fig. 2313.—Lines of skin incision for amputations at the metatarso-phalangeal joints. Note the flaps for the hallux and little toe.

removed, it is usually advisable to amputate all the toes including the hallux at the metatarso-phalangeal joints, and to remove the head of the 5th metatarsal.

(4) *Amputation of the hallux* (*big toe*): (*a*) The amputation through the interphalangeal joint is carried out as in the case of the other toes, but it is usually easier to open the joint from the dorsum and to carry the knife along the plantar aspect of the phalanx, i.e. to cut the flaps from within outwards.

(*b*) Racket incision is used for the amputation through the metatarso-phalangeal joint, but the handle of the racket is placed on the outer (little toe) side of the metatarsal bone. The flaps should be cut unequal, the larger one being along the inner side of the toe. This is done to prevent the scar being exposed to pressure from the shoe. Care must be taken that there is no tension over the metatarsal head. A modification of this operation is to cut through the 1st phalanx just distal to its base and to leave this attached to the metatarsal, thereby producing a better stump.

AMPUTATIONS THROUGH THE FOOT

These are seldom satisfactory. The standard amputations are:

(1) *Through the metatarsus* at any level.

(2) *Lisfranc's amputation,* and its modifications by Hey and Skey. The more of the foot that can be left the better, as a padded boot will be more comfortable and serviceable. The advantages of a flap from the sole are that the tissues on the sole are thicker and more vascular, and that the scar will be placed on the dorsum. These operations are not suitable if there is an equinus deformity which cannot be corrected.

(3) *Chopart's mid-tarsal amputation,* which consists in disarticulation of the foot through the astragalo-scaphoid and calcaneo-cuboid joints, so that the astragalus and os calcis remain on the limb. A long plantar flap is used. The operation is performed on the Continent and in Scotland, but it is not regarded with favour in England, owing to the equinovarus deformity of the stump which frequently follows. Fixation of the peronei and extensor muscles to the outer side of the astragalus and os calcis can be employed in an attempt to prevent this.

AMPUTATION AT THE ANKLE JOINT

Syme's amputation consists in using the heel as a covering to the lower end of the tibia and fibula, just above the ankle joint. It should not be employed if there is scar tissue in the skin of the heel, or in the presence of any gross infection in the foot. The details of the classical operation, originally described nearly one hundred years ago, have been somewhat modified, as the flap was found to be too large.

A sand-bag is placed under the leg, and the lower third of the leg protrudes over the end of the table. The operator stands at the end of the table facing the sole of the foot.

(1) *Skin flap.* The incision is elliptical, extending from above the ankle joint in front to 1 inch in front of the point of the heel. For the *right* foot, the incision begins on the outer side of the heel 1 inch in front of the point of the heel and is carried upwards over the tip of the external malleolus forwards and upwards to 1 inch above the ankle joint. It then passes downwards, crossing a point ½-inch below and in front of the tip of the internal malleolus to the side of the heel 1 inch in front of the point of the heel. A transverse incision across the heel joins the two ends of the incision (see fig. 2314).

For the *left* foot, the incision is commenced on the inner side of the heel, 1 inch in front of the point of the heel, and is carried round in the

reverse direction. The knife should penetrate right down to the bone all round the incision.

(2) *Disarticulation.* The foot is plantar flexed by the assistant, and a strong scalpel is used to divide in turn the anterior ligament of the

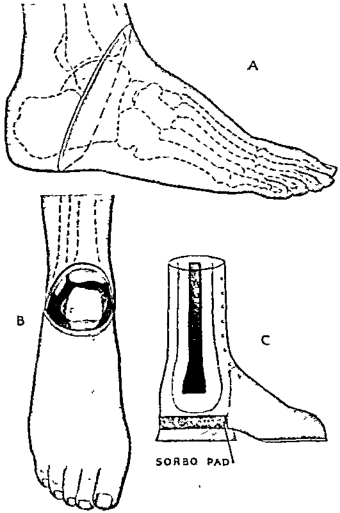

Fig. 2314.—Modified Syme's amputation.

A. The skin incision.
B. The ankle joint open in front.
C. Diagrammatic section of a suitable boot, showing the stump in the boot.

ankle joint, the lateral ligaments (from within outwards), and the posterior ligaments.

(3) *Dissection of the os calcis.* The foot must be kept plantar flexed while the surgeon dissects the tendo Achillis and heel pad of fat from the os calcis. The knife must be kept close to the bone during this procedure, the dissection being carried out by a series of incisions on to the bone.

(4) *Removal of the lower ends of the tibia and fibula.* The skin flap is retracted, and an incision made through the periosteum ½-inch above the level of the ankle joint and at right angles to the long axis of the leg.

The periosteum is gently pushed up with a broad fan-shaped elevator. The tibia and fibula are then sawn across not less than ½-inch above the joint, care being taken that the line of the division of bone is at right angles to the shaft of the tibia.

(5) *Soft structures.* The anterior tibial vessels and the internal saphenous vein require ligation, and the anterior tibial and musculo-cutaneous nerves, although small, should be picked up, drawn down, crushed and ligated. The plantar vessels are ligated, and the nerves dissected from the flap. The latter should be dissected up to the posterior tibial nerve, which is of considerable size. The nerve is crushed and ligated as far up as possible above the level of bone division. Other small vessels may require ligatures. Any tendons which have not retracted are drawn down and divided.

(6) *Closure of the wound and drainage.* The stump is bathed with saline at 120° F. and the flap sutured, care being taken that the mid-point of the heel flap is sutured to the mid-point in front. A small drain is inserted into each corner of the incision for two days. A drainage-tube should not be placed through a puncture wound in the heel flap.

This amputation produces an end-bearing stump, on which the patient can walk in six weeks. The simplest appliance worn is an "elephant boot," i.e. a boot with a strong broad heel, the leg piece of which is laced up the front like a long lace-up riding boot. This is usually more satisfactory than the more expensive and elaborate appliance which has a platform and side steels and an ankle movement device with rubber buffers below.

AMPUTATIONS THROUGH THE LEG

The standard operation provides a 7-inch stump of tibia, and is an excellent amputation when there is full movement at the knee joint. If only 5 inches of tibia are available, the function is nearly as good. With 4 inches of tibia the patient can manage an artificial limb, if his thigh and stump are not very large. When less than that is available, an above-knee amputation is advisable, unless he is to use a peg-leg with a flexed knee. By means of the latter, weight-bearing is taken on the anterior surface of the stump, which is flexed to a right angle. Such an appliance was provided when amputation at the site of election was practised. Amputation in the lower third of the leg is undesirable as the scar and flaps are liable to congestion and ulceration.

Mid-leg amputation. (1) The *skin incision* consists of a large anterior and a short posterior flap (or of a large anterior flap only, equal

in length to the diameter of the leg at the level of bone section). A length of tibia, 7 inches long from the knee joint, is measured and the point noted. The diameter of the leg at this level is measured, and a large anterior flap cut, measuring in length three-quarters of the diameter and in width half the circumference of the limb, so that the lateral incisions are just behind vertical lines drawn upwards from the malleoli. The transverse incision over the calf joins the upper third of the anterior skin flap (fig. 2315); this should be carried down to the

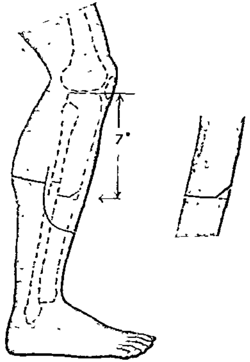

Fig. 2315.—Mid-leg amputation. The skin flap is marked out and the lines of division of the tibia and fibula are indicated.

bones. The flaps are cut so that the corners are rounded, and are reflected.

(2) The *muscles* in the front of the leg and interosseous membrane are divided. The periosteum of the tibia is divided and pushed up for half an inch.

(3) The saw is applied obliquely to the tibia one-third of an inch above the level at which it is intended to divide the bone. When it has been cut half through, the saw is removed and a transverse cut made across the tibia, the wedge-shaped piece of bone falling out, so that the line of division of the tibia is an obtuse angle. The fibula is then divided 1 inch above the level at which the tibia was divided. This can be done by a strong pair of bone-cutting forceps of the laminectomy type, care being taken that the bone is not splintered.

(4) The *vessels* are ligated, including the saphenous veins. Some

small vessels in the calf muscles require attention. It is very important to deal efficiently with the anterior and posterior tibial and the musculo-cutaneous nerves.

(5) The *flaps* are sutured, and should fit neatly. If they have been cut too long, so that they are loose over the ends of the bone, one flap should be shortened. A drainage-tube should be inserted across the stump. The scar will be placed *on the posterior aspect of the limb.* The knee joint should be kept extended during the convalescence.

The use of lateral flaps, producing a scar which is intended to be between the two bones, is less satisfactory than the method just described. It is possible to suture a portion of gastrocnemius over the tibia, but this is unnecessary.

Artificial Limb. The bucket consists of willow wood, duralumin, or leather reinforced by steel strips. Some makers insert a lining leather case which takes a bearing on the top of the bucket, to prevent the stump, especially if short, from slipping out. Pressure is taken by the head of the tibia and slightly by the lower border of the patella (fig. 2316).

The bucket is joined to a leather thigh corset and shoulder braces. A popliteal check cord or accumulator is fitted to prevent hyperextension of the knee. A jointed mechanism is used at the knee joint

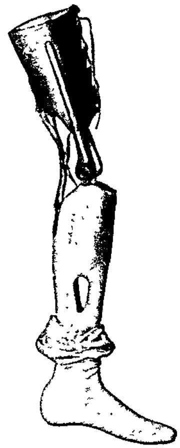

Fig. 2316.—Artificial limb used for leg amputations. The thigh control bucket is of moulded leather. (*Beckett and Bird.*)

AMPUTATIONS IN THE REGION OF THE KNEE

The three operations which are classical are termed: (1) Disarticulation of the knee joint (often called Stephen Smith's); (2) Stokes-Gritti's amputation; and (3) Carden's method. They were all designed to produce a weight-bearing stump. Artificial limbs made at the present time cannot be fitted to these stumps satisfactorily, and the patient profits by a shorter stump with weight-bearing on the tuber ischii. *The operations are rarely carried out, either in this country or in France* and Germany. A report compiled from statistics from the latter two countries shows that there were 17 disarticulations at the knee joint to 507 amputations of the thigh. In this country probably still fewer disarticulations would be recorded. The disarticulation will be chosen

in length to the diameter of the leg at the level of bone section). A length of tibia, 7 inches long from the knee joint, is measured and the point noted. The diameter of the leg at this level is measured, and a large anterior flap cut, measuring in length three-quarters of the diameter and in width half the circumference of the limb, so that the lateral incisions are just behind vertical lines drawn upwards from the malleoli. The transverse incision over the calf joins the upper third of the anterior skin flap (fig. 2315). this should be carried down to the

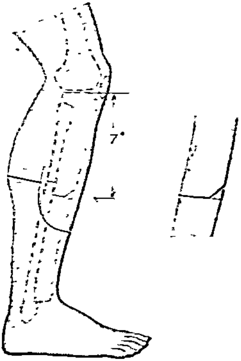

Fig. 2315.—Mid-leg amputation. The skin flap is marked out and the lines of division of the tibia and fibula are indicated.

bones. The flaps are cut so that the corners are rounded, and are reflected.

(2) The *muscles* in the front of the leg and interosseous membrane are divided. The periosteum of the tibia is divided and pushed up for half an inch.

(3) The saw is applied obliquely to the tibia one-third of an inch above the level at which it is intended to divide the bone. When it has been cut half through, the saw is removed and a transverse cut made across the tibia, the wedge-shaped piece of bone falling out, so that the line of division of the tibia is an obtuse angle. The fibula is then divided 1 inch above the level at which the tibia was divided. This can be done by a strong pair of bone-cutting forceps of the laminectomy type, care being taken that the bone is not splintered.

(4) The *vessels* are ligated, including the saphenous veins. Some

small vessels in the calf muscles require attention. It is very important to deal efficiently with the anterior and posterior tibial and the musculo-cutaneous nerves.

(5) The *flaps* are sutured, and should fit neatly. If they have been cut too long, so that they are loose over the ends of the bone, one flap should be shortened. A drainage-tube should be inserted across the stump. The scar will be placed on the posterior aspect of the limb. The knee joint should be kept extended during the convalescence.

The use of lateral flaps, producing a scar which is intended to be between the two bones, is less satisfactory than the method just described. It is possible to suture a portion of gastrocnemius over the tibia, but this is unnecessary.

Artificial Limb. The bucket consists of willow wood, duralumin, or leather reinforced by steel strips. Some makers insert a lining leather case which takes a bearing on the top of the bucket, to prevent the stump, especially if short, from slipping out. Pressure is taken by the head of the tibia and slightly by the lower border of the patella (fig. 2316).

The bucket is joined to a leather thigh corset and shoulder braces. A popliteal check cord or accumulator is fitted to prevent hyperextension of the knee. A jointed mechanism is used at the knee joint.

AMPUTATIONS IN THE REGION OF THE KNEE

The three operations which are classical are termed: (1) Disarticulation of the knee joint (often called Stephen Smith's); (2) Stokes-Gritti's amputation; and (3) Carden's method. They were all designed to produce a weight-bearing stump. Artificial limbs made at the present time cannot be fitted to these stumps satisfactorily, and the patient profits by a shorter stump with weight-bearing on the tuber ischii. The operations are rarely carried out, either in this country or in France and Germany. A report compiled from statistics from the latter two countries shows that there were 17 disarticulations at the knee joint to 507 amputations of the thigh. In this country probably still fewer disarticulations would be recorded. The disarticulation will be chosen

by a few surgeons in feeble elderly subjects, as a life-saving measure in cases of gangrene, *in some cases of gunshot wound of the leg as a* primary operation, and in a few patients who, owing to congenital abnormality or previous injury, have been accustomed to weight-bearing on a flexed knee.

AMPUTATION THROUGH THE THIGH

The operation of choice is by an anterior flap with division of the femour $2\frac{1}{2}$ inches above the level of the knee joint (fig. 2317). It is frequently employed in cases of injury, gangrene of the foot and leg, tuberculous disease of the knee joint, and sarcoma of the leg.

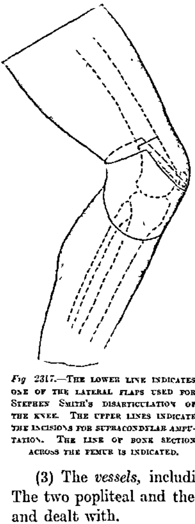

Fig 2317.—THE LOWER LINE INDICATES ONE OF THE LATERAL FLAPS USED FOR STEPHEN SMITH'S DISARTICULATION OF THE KNEE. THE UPPER LINES INDICATE THE INCISIONS FOR SUPRACONDYLAR AMPUTATION. THE LINE OF BONE SECTION ACROSS THE FEMUR IS INDICATED.

(1) *The skin flap* is equal in width to the diameter, and in length to two-thirds of the diameter of the limb (see fig. 2317). This is quite sufficient as the skin stretches easily in this region. This flap is reflected, and the rectus tendon and quadriceps muscle are divided above the patella and similarly reflected. The posterior incision is then made transversely across the popliteal space, joining the two ends of the base of the flap. The hamstring muscles are divided in the same line. The remaining muscles, vessels and nerves are picked up with artery forceps and divided.

(2) A muscle retractor is placed over the muscle. The periosteum is cut cleanly and pressed upwards, and the femur is sawn through, $2\frac{1}{2}$ inches above the knee joint.

(3) The *vessels*, including the internal saphenous vein, are ligated. The two popliteal and the long saphenous nerves should be identified and dealt with.

(4) *The hamstring muscles* are now sutured to the quadriceps, the stitches passing through the muscular sheath as well as the muscle, so that a good covering for the bone is formed. Care should be taken that the bone is in the centre of the muscular tissue, which has a tendency to slide sideways.

The skin flap is sutured and a drainage-tube inserted. The scar will lie posteriorly.

Note 1. This amputation may be performed after circular, elliptical, equal or unequal lateral or antero-posterior skin flaps.

Note 2. If this operation is performed for tuberculous disease of the knee joint, care must be taken to avoid infecting the wound. The suprapatellar pouch and any other infected area should be dissected out at as early a stage of the operation as possible, and clean instruments should then be employed.

Note 3. During convalescence this stump must not be allowed to become flexed at the hip joint.

Mid-thigh amputation. As much length of bone as possible should be preserved. If the foregoing amputation cannot be carried out,

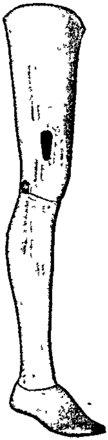

Fig. 2318.—Artificial limb used after thigh amputations. The "accumulator elastic" mechanism for knee joint control is within the limb. The straps for fixation to the trunk are not shown.

(*Beckett and Bird.*)

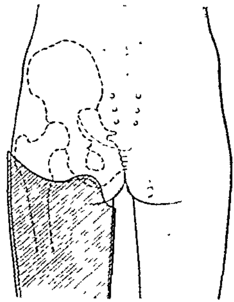

Fig 2319.—Bucket of artificial limb fitting the ischial tuberosity (seen from behind).

a useful stump can be obtained with the bone divided at a higher level. Muscle retraction hardly ever occurs in amputation above the middle of the thigh. Preventive treatment of spurs is advisable (see page 4273).

Artificial appliance. A pylon should be worn before the stump is ready for the permanent appliance, which consists of a bucket of wood or light metal, attached by side steels to the leg and foot-piece (fig. 2318). There are joints at the knee, which allow a definite range of movement, and here is an elastic or cord appliance to prevent hyperextension of the knee. The foot mechanism allows

a rocking movement and in most limbs allows movement at the level of the ankle joint and behind the toes The weight of the body is transmitted from the tuber ischii to a small rounded platform at the top of the bucket (see fig. 2319). It is essential for the patient to learn to sit on this platform.

DISARTICULATION OF THE HIP JOINT

This operation is employed in cases of tumours and extensive necrosis of the femur, and rarely in severe injuries of the thigh and in some cases of tuberculosis of the hip joint with secondary infection, also in the case of a limb completely flail from anterior poliomyelitis.

Although hæmorrhage and shock are reputed to be serious and immediate dangers, this should not be the case if the patient is prepared for the operation and if the technique for hæmostasis is efficient. If the patient is in a poor state of health, blood or saline transfusion should be employed prior to the operation, and vessels should be clamped before they are divided.

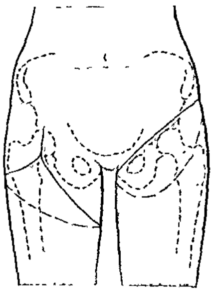

Fig 2320—On the right thigh is shown the racket incision employed for disarticulation at the hip joint. On the left, the posterior flap and anterior incision are depicted in the Fitzmaurice Kelly disarticulation.

The "stump" consists of the pelvis covered by skin and subcutaneous tissue, or, exceptionally, the head of the femur (or more) is left in the acetabulum. As the artificial appliance will not fit over a flabby mass of muscle and loose skin, redundant tissue should be trimmed away.

The operations usually employed are :

(1) *The anterior racket method*, which is the easier operation; and

(2) *Disarticulation by a posterior flap* (*Fitzmaurice Kelly*). For either operation the patient is seated on a sand-bag 3 inches deep at the end of the operating table, and the opposite limb is drawn away. The skin over the lower abdomen, pubes and perineum is included in the preparation for the operation.

Anterior racket method. This is suitable for amputation with division of the femur high up or for disarticulation.

(*a*) *Skin incision* (see fig. 2320—right thigh). The incision starts over the vessels at the level of Poupart's ligament and is carried down in the line of the vessels for 4 inches. It then passes obliquely round the inner side of the thigh, crossing the adductor muscles 4 inches

below the perineum. The femoral vessels are exposed, ligated separately, and divided between ligatures. The skin incision is then continued across the back of the thigh and over the great trochanter to join the original incision.

(*b*) *Muscles* on the front of the thigh are divided and the joint capsule opened in front. The other muscles are divided, vessels being clamped before division whenever possible. After division of the posterior part of the capsule, the limb is removed.

(*c*) The nerves are dealt with as described previously.

(*d*) Trimming of the flaps may be necessary; the wound is sutured and drained at the outer corner of the wound.

Posterior flap method. (*a*) *Skin incision* (see fig. 2320—left thigh). An incision is made obliquely across the front of the thigh, parallel to Poupart's ligament, from outside the anterior superior iliac spine inwards. The vessels and anterior crural nerve are isolated and divided between ligatures. A posterior flap is marked out, so that when brought forward the stump will be covered without tension. It is a semicircular flap, in length as great as the diameter of the top of the limb from before backwards. It is dissected up as far as the sciatic notch.

(*b*) The muscles are divided close to the pelvis, at first in front and then medially and laterally, leaving the posterior muscles until last, the vessels being clamped prior to division.

(*c*) The femur is disarticulated after division of the capsule.

(*d*) The flaps are trimmed so that the posterior flap fits snugly over the bony prominence, and the suture line is parallel to Poupart's ligament. The drainage-tube is placed at the inner end of the wound or 2 inches from this point.

Fig. 2321.—"Tilting table" artificial limb used after disarticulation of the hip joint.

(*Beckett and Ford.*)

Artificial limb. This consists of a "tilting table" limb fitting to the tuber ischii and to the outer surface of the pelvis (see fig. 2321). It should be made to fit *closely, both in the walking and the sitting positions.* This "tilting table" is fixed to a thigh piece, between which is a hinge which the patient can unlock when he sits down. The leg and foot are mainly similar to those in other lower limb appliances. Pelvic bands and shoulder braces are necessary.

HIND-QUARTER (INTERINNOMINO-ABDOMINAL) AMPUTATION

This operation is known to have been performed in seventy-nine cases with a mortality of 59 per cent. It has generally been performed for tumours of the innominate bone and the upper portion of the femur. Gordon-Taylor and Wiles state that "the important points in the conduct of the operation are: (1) The most gentle care in turning the patient; the danger from rough or excessive movement of the patient under spinal anæsthesia cannot be exaggerated. (2) The most thorough organisation of blood-transfusion arrangements. (3) Division of the posterior portion of the dorsum ilii with the saw is more expeditious and simple than disarticulation of the bone at the sacro-iliac synchondrosis; it is easy subsequently to oblate the auricular portion of the ilium. (4) It is necessary to stress the importance of minimising hæmorrhage and shock by preliminary control of vessels before division, and of nerve blocking before section of the trunks."

These writers' description of the operation should be carefully studied by anyone contemplating this colossal operation. (Gordon-Taylor and Wiles, *British Journal of Surgery*, 1935, XXII, 88.)

THE UPPER EXTREMITY

AMPUTATION OF THE FINGERS

This operation is usually required in cases of injury or subsequent *to infection.* The general rule is that amputation should be delayed as long as possible In considering removal of the fingers, it is useful to realise that the question of amputation arises: (*a*) Immediately after injury: (*b*) during the acute stage of infection in a finger; and (*c*) when the results of injury or infection remain.

(*a*) Immediately after injury, it often appears that laceration of skin, division of tendons, and fracture of phalanges are so extensive that a useful finger cannot be obtained. Immediate amputation just above the level of the proximal fracture will be the correct treatment if sufficient skin is available. This will be successful if the wound heals by primary union, as is likely if the operation is carried out within a few hours of the injury. If an attempt is made to save the part, infection may supervene, so that it may be difficult to decide when to amputate,

and this may have to be done at a higher level. However, if no surgical treatment, such as efficient cleansing of the part, is carried out for twenty-four hours, a primary amputation is likely to be followed by an infected stump. Consequently, if this delay has occurred, it is advisable to take all steps to prevent spread of infection and to amputate at a later date.

(*b*) It is unwise and rarely necessary to amputate a finger while a thecal whitlow is acute or when a sequestrum from a phalanx is present, surrounded by infected granulation tissue. In such cases, except when septicæmia has arisen, treatment should be directed towards saving the finger.

(*c*) This group comprises the end-results of groups *a* and *b*. The amputation is in the nature of a "set operation" and is carried out preferably when there is no sinus or unhealed scar. Amputation is recommended in these cases, owing to a portion or the whole of the finger being useless and often preventing other fingers from carrying out their full function.

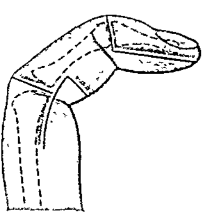

Fig. 2322.—Skin flaps employed in amputation through the terminal and first interphalangeal joint of a finger.

(1) *Amputation at the terminal phalanx.* The tip of the finger is held in the left hand and the terminal phalanx is fully flexed. With a small scalpel a transverse incision is made across the dorsum of the finger a quarter of an inch distal to the last bend of the finger (fig. 2322). This passes through skin and extensor tendon and enters the joint. The lateral ligaments are divided, and the scalpel is then turned so that the cutting edge is towards the end of the finger. The incision is then carried on to make sufficient palmar flap, and the amputated portion is removed. The palmar flap is stitched back so that the scar is on the dorsum. The bleeding will generally cease without the application of any ligatures.

(2) *Amputation through the second or first phalanx,* or at the first interphalangeal joint, is carried out by a palmar or equal lateral flaps. Amputation through the proximal end of the second phalanx is not advisable. The digital vessels require ligation, and it is most important to search for the digital nerves, pull them down, and crush and ligate each in turn, as a small neurofibroma, particularly when attached to the scar, is likely to be painful. The skin flaps are the only covering necessary, suture of the tendons being of no functional value, since the first phalanx is flexed by the interossei muscles.

(3) *Disarticulation at the metacarpo-phalangeal joint.* Whatever skin flaps are cut, these should be sufficiently large to allow full range of abduction of the neighbouring fingers. Although flaps can be formed from any surface, the surgeon should aim at avoiding any scar on the palmar aspect. The *middle* and *ring* fingers are most easily removed by a racket incision. This is marked out first (fig. 2323). The extensor tendon is divided and the joint opened on the dorsum. The knife is kept close to the bone whilst separating the phalanx from the metacarpal head, and the palmar structures are divided. The digital vessels and nerves are then picked up and dealt with.

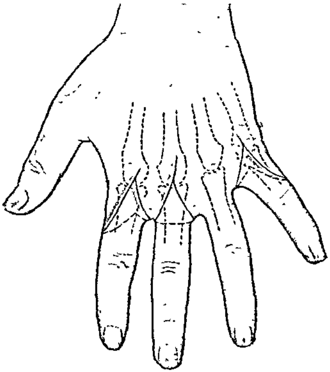

Fig. 2323.—Lines of skin incision used for amputation of little, middle and index fingers. Note the lateral flaps used for index and little fingers.

The flaps for the *index* and *little* fingers should be cut so that the scar is protected This is carried out in the case of the index finger by using a flap cut from the thumb side, and the incision on the other side of the finger extends right down to the web (see fig. 2323). For the little finger the larger flap is cut from the ulnar aspect of the finger.

Discussion arises concerning the advisability of removing the head of the metacarpal bone, instead of disarticulating through the metacarpo-phalangeal joint. A stronger hand remains if the metacarpal head is left in place, and a glove with dummy finger fits better. If the head of the metacarpal bone of the ring or middle finger is removed, the appearance of the hand is less unsightly, as the fingers will fall

together, but strength of the hand will be sacrificed for the sake of this improved appearance. The appearance of the stumps of the index and little fingers will be improved by cutting off the part of the head obliquely, and this weakens the hand less than complete removal of the head. The radial half is removed obliquely in the index finger and the ulnar half in the little finger.

(4) *Amputation of a finger with the metacarpal bone.* This operation is seldom required, except in cases of injury to bone and tendons, when the amputation is usually not limited to one digit. The surgeon has to use his discretion as to the level of amputation, possibly through two or more metacarpal bones. This is the type of case when delay in the amputation is desirable if possible.

The amputation is often carried out as a practical exercise.

An incision is made over the whole length of the metacarpal bone and carried round the base of the finger just distal to the web. The periosteum of the bone is incised and the bone cut through its shaft just distal to the base. The bone is thereby removed subperiosteally, so that there is no interference with the muscular attachments.

AMPUTATION OF THE THUMB

This is required in cases of injury and, rarely, of disease. It is not carried out as a set operation, for any operative procedure is performed with the object of preserving all possible tissue. Stiffness of the joint is so small an incapacity compared with the loss of any tissue of the thumb that it need hardly be considered if the surgeon contemplates amputating a portion of the thumb. When the thumb has to be trimmed after injury, an attempt should be made to make scars on the dorsum. If there is not sufficient skin to cover the injured area, this is no indication to amputate, as the area can be grafted with skin at a later date. When it is necessary to remove bone, this should be done subperiosteally. If the attachments of the short thumb muscles are injured, these should be sutured to the neck of the metacarpal, or if the terminal phalanx has to be removed, they should be fixed over the head of the metacarpal bone.

DISARTICULATION AT THE WRIST JOINT

This operation is rarely employed, for injuries of the hand either enable the surgeon to preserve a portion of the hand, or else injure the wrist as well so that amputation at a higher level is necessary. It is seldom called for in tuberculous or septic disease or in tumours of the hand. The advantage of disarticulation at the wrist over amputation at a higher level is that pronation and supination are still possible.

(1) *Skin incision.* The choice lies between a palmar flap and a circular incision 1 to $1\frac{1}{2}$ inches below the styloid process of the radius. In injury the flaps may have to be cut in an irregular way owing to skin laceration. The *palmar flap* consists of a rectangular flap with two rounded corners. It begins just below the styloid process of the radius and is carried over the ball of the thumb in the direction of the index finger. At the level of the outstretched thumb, the knife is carried across the palm at right angles. When it comes opposite the space between the ring and little fingers, it is carried upwards towards the styloid process of the ulna, stopping short of this by $\frac{1}{2}$-inch. This flap is dissected up so as to include the muscles of the thenar and hypothenar eminences, the palmaris longus, the terminal branches of the ulnar artery and nerve, and the pisiform bone if this is healthy. The posterior incision, which is carried across the dorsum of the wrist so as to join the base of the palmar flap, is made down to the bones.

(2) *Disarticulation.* The ligaments are divided on the dorsum and the carpus disarticulated from the radius and ulna.

(3) *Soft parts.* The flexor tendons are divided, as are also the anterior ligaments. The radial, ulnar and terminal branches of the interosseous arteries are ligated, and the median, ulnar and radial nerves are secured and dealt with. The styloid processes are cut flush with the articular surfaces of the radius and ulna. The tendons are further cut short if necessary, but some surgeons consider that better function is obtained by suturing flexor to extensor tendons over the ends of the bone. Drainage is advisable after skin suture.

AMPUTATION THROUGH THE FOREARM

This is required after severe injuries and for advanced tuberculosis or infection of the hand. The longer the stump, the better control will the patient have of the artificial appliance. Every effort should be made to perform the bone section below the insertion of the pronator radii teres, as ability to pronate and supinate is advantageous. If the amputation has to be done at a higher level, 3 inches of ulna are necessary in a forearm stump in order to control the bucket; for although the latter may sit well to a short stump with the elbow extended, it is too tight when the joint is flexed, owing to the bulk of the muscles in the front of the elbow on flexion.

The skin flaps often have to be fashioned from such skin as is available. As a terminal scar is as satisfactory as any, it is of little importance whether the skin is cut by the circular, antero-posterior or lateral method. The flaps should be short, as the skin stretches readily. To

carry out the amputation, the limb is abducted from the thumb and the forearm supinated. After reflection of the skin by one of the flap methods indicated, the muscles are divided transversely. The periosteum is divided neatly and pushed upwards prior to division of the radius, which is cut through first. The vessels and nerves are then dealt with. The muscles are sutured over the ends of the bone and between the two bones, because free stripping of the periosteum and this muscular strip between the bones should prevent bony ankylosis between the ends of the radius and ulna. This is the usual sequence if no effort is made to prevent it. Fusion of the bones abolishes pronation and supination.

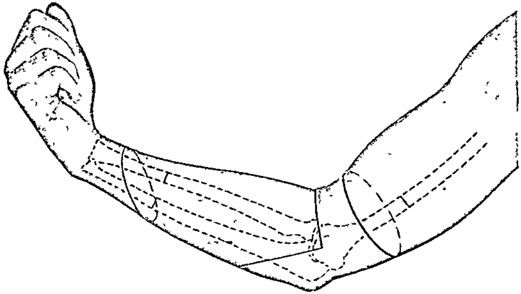

Fig 2324.—The line nearest the wrist shows the elliptical incision for low forearm amputation and the line of bone section. The flaps at the elbow are those used for disarticulation. The circular incision is shown for amputation of the lower third of the arm, with the line of bone section.

DISARTICULATION AT THE ELBOW JOINT

This operation is not often performed, because in most cases, when it is indicated, sufficient skin is not available, and amputation through the lower part of the arm is chosen instead. It is indicated in extensive injuries of the forearm, when the upper three inches of the ulna cannot be preserved, or when there is insufficient skin available to cover that length of radius and ulna. It is inadvisable to employ disarticulation of the elbow for malignant growths in any part of the forearm because the whole length of the forearm muscles should be removed, and this necessitates amputation above their origin from the humerus. The shape of the stump produced after disarticulation is broad from side to side and flat from before backwards, owing to the shape of the lower end of the humerus. At first sight this odd shape appears difficult to fit with an artificial appliance, but it is found that it has a considerable

advantage over the round stump of low arm amputations in that prominence of the condyles prevents rotation of the artificial limb on the stump.

(1) *Skin flaps.* These depend on the skin available, and the surgeon should aim at making use of one of the three recognised methods of cutting flaps. The limb should be extended and supinated when the skin is marked out.

(*a*) *Circular*, in which the skin flap runs slightly obliquely, being three finger-breadths below the joint line on the radial side, and two on the ulnar. When cut in the circular manner, the skin will retract more on the radial side.

(*b*) *Elliptical*, in which the anterior part of the ellipse corresponds to the fold in front of the elbow, while posteriorly it crosses the ulna a hand's breadth below the joint.

(*c*) *By flaps, preferably a posterior flap.* This consists of a semicircular flap from epicondyle to epicondyle, the length of flap as measured from the tip of the olecranon being equal to the antero-posterior diameter of the upper end of the forearm. It is cut with the elbow flexed to a right angle. The anterior incision joins the epicondyle across the fold of the elbow, and is made with the arm extended (see fig. 2324).

(2) *Soft tissues* are divided down to the joint across the front of the elbow.

(3) *The disarticulation* is begun on the outer side, by dividing the ligaments and entering the joint between the capitellum and the head of the radius. When the coronoid process of the ulna is free from the humerus, the forearm is hyperextended and the posterior ligaments and attachment of the triceps are divided from the front.

(4) *Vessels and nerves.* Superficial veins, and the brachial, terminal branches of the superior and inferior profunda, and anastomotic arteries require ligation. The median, ulnar and musculo-spiral nerves require shortening, crushing and ligation. The musculo-cutaneous and internal cutaneous nerves should be dissected out and dealt with in a similar manner.

Drainage of the wound is advisable.

AMPUTATION THROUGH THE ARM

This amputation is easier to perform than many, as there is one bone in the centre and muscles are arranged compactly around it. It is indicated in cases of severe injury, neoplasm, and septic and tuberculous arthritis of the elbow joint.

The longer the stump, the greater the control of the artificial limb. A stump at the level of the axillary fold cannot control an appliance. Owing to the elasticity of the skin, this will pull down readily, and $4\frac{1}{2}$ inches of humerus, with the end covered with skin only, is of much greater value than 3 inches well covered with muscle and skin. It is usually possible to cover the end of the bone when this is divided at the same level as the skin.

The limb is abducted to a right angle. For amputations in the lower third of the arm a tourniquet is applied; above that level, an assistant can compress the subclavian artery, but the method of choice is to dissect out the large veins when cutting the skin flaps and then to expose the brachial artery and ligate it, the other vessels being picked up as they are exposed. Alternatively, all the soft tissues are divided quickly with one incision and the vessels immediately picked up.

The method of cutting the skin is usually circular, but flaps or an ellipse are equally suitable.

Artificial Hands and Arms

After amputations of the hand, an artificial hand made of wood or leather is used, covered with a glove. The appearance of this is usually the first thought of the patient, but he should be encouraged to use various appliances which can be fixed to the end of the bucket in place of the hand. A knife, fork, hook and tools are of greater value than articulated fingers. After amputations at a higher level, a corset is fitted to the upper arm, and a hinge is placed at the elbow if the patient can control this joint, or an artificial locking elbow after amputation at the joint or above. A metal or leather forearm bucket is used for the forearm. A shoulder cap and chest belt extending round the opposite axilla are necessary in amputation above the elbow. Careful arrangement of straps from the shoulder cap to the arm bucket or corset aids the movement at the shoulder.

DISARTICULATION AT THE SHOULDER JOINT

This operation is seldom required except for severe injuries of the arm when the upper end of the humerus is fragmented. In malignant disease of the humerus, it may be employed if the intention of the surgeon is to rid the patient of a growth which has ulcerated, or is about to do so, through the skin. The forequarter amputation is likely to be the operation of choice in sarcoma of the humerus, but this may be contra-indicated by the patient's general condition. Disarticulation at the shoulder may be modified by dividing the humerus at the anatomical neck and leaving the head in the glenoid, thus preventing the extreme flattening of the shoulder.

The operation of choice is a modification of Spence's, which enables

the operator to limit the hæmorrhage. The arm is abducted 45 degrees from the trunk and externally rotated.

(1) *Skin flap.* The coracoid process is located and the incision made from this point downwards in the long axis of the arm to the lower border of the anterior axillary fold. It then passes outwards over the deltoid and round the arm to the posterior axillary fold. It is continued forwards and upwards to join the vertical incision (fig. 2325).

The flap on the inner side is dissected up, and the pectoralis major divided. In cases of injury, this is cut close to the humerus, but in malignant disease, as far away as possible.

(2) *Vessels and nerves.* The axillary artery and vein are clamped at the level of the shoulder joint and divided between ligatures. The nerves of the brachial plexus are clamped, pulled down, reclamped, and ligated before division.

(3) *Disarticulation.* The external flap is dissected up and retracted with the greater part of the deltoid muscle adherent to the flap, except in cases of malignant disease.

Both heads of the biceps are divided and the joint opened in front. The knife is then applied to the humerus, so as to divide the muscles attached to the tuberosities and neck. The posterior portion of the capsule is divided and the limb is removed. A number of bleeding points will then require attention. The wound is closed and drained.

Note The tendency is to cut the flaps too long, so that the axillary scar is redundant and the folds of skin tend to cause trouble. Hence, if there appears to be excess of skin, this should be trimmed before closing the wound.

FOREQUARTER (INTERSCAPULO-THORACIC) AMPUTATION

This extensive operation (fig. 2325) is usually performed in cases of sarcoma of the upper end of the humerus, whether the shoulder joint is involved or not. It is rarely used for injury, acute gangrene, or infective conditions of the upper limb. The amputation is usually carried out as originally described by Berger in 1887. This involves the removal of the upper limb, scapula, and part of the clavicle, with division of the muscles close to the latter two bones. Pre-operative transfusion of blood may be advisable.

(1) *Position of the patient.* The patient lies on his back with the shoulder of the affected side overhanging the side of the table. A second assistant holds the upper limb. The position may be kept constant by placing a sand-bag under the unaffected shoulder.

(2) *Exposure of main vessels.* An incision is made commencing over the sterno-clavicular joint and extending along the upper border of the

inner two-thirds of the clavicle. The clavicle is cleared of muscle and periosteum, so that it can be divided, preferably with a Gigli or 2-inch bladed saw, at the junction of the middle and inner thirds. The outer portion of the bone is then drawn outwards and upwards and the subclavius muscle and fascia carefully divided so as to expose the subclavian vessels and brachial plexus. In order to have greater space some surgeons prefer to resect the middle third of the clavicle, dividing the bone at the inner point first and then stripping the posterior surface before dividing the junction of the middle and outer thirds.

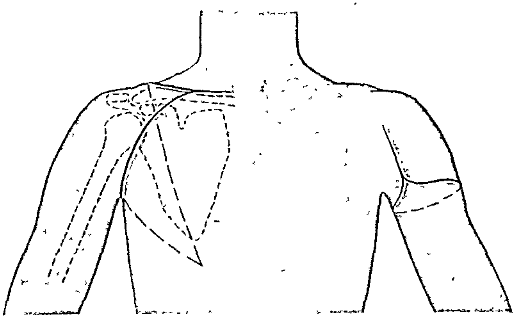

Fig. 2325.—On the left shoulder the skin incision for disarticulation at the shoulder joint is indicated. On the right shoulder is shown the skin incision for forequarter amputation.

(3) *Division of vessels and nerves.* Each trunk of the plexus is injected with 1 per cent novocaine, crushed just distal to the swelling caused by the injection, ligated, and divided with a sharp scalpel. The subclavian artery and vein are divided between ligatures at the level of the first rib. The suprascapular and posterior scapular arteries are ligated as they pass laterally in front of the scalene muscles.

(4) *The anterior dissection.* The arm is abducted almost to a right angle with the trunk. The outer end of the skin incision is continued by carrying it over the coracoid process downwards and outwards across the anterior axillary fold. It then passes backwards across the axilla and down the chest wall to the inferior angle of the scapula. This flap is dissected inwards. The pectoralis major is dissected up and divided close to the thorax, the vessels being picked up before division. The axilla and lateral chest wall are dissected downwards, stripping the

which might be ruptured. The majority of surgeons consider that in patients over the age of fifty a tourniquet should not be employed. When a tourniquet is used, the question will arise as to when it should be removed. The usual custom is to remove it as the dressing is being applied. Such dressing should include a considerable quantity of good quality wool and should be bandaged firmly. If the surgeon wishes to remove the tourniquet before closing the wound, it is essential that he should ligature a large number of small vessels before closing the wound and applying the dressing. The method of retaining the tourniquet until the dressing has been applied is more popular at the present time. Undoubtedly it is to the patient's advantage that there should be no hæmatoma either into a reconstructed joint or subcutaneously, particularly as a hæmatoma encourages infection and subsequent ankylosis; but post-operative hæmatoma will occur in a proportion of cases operated on under a tourniquet. These operations can be carried out with so much greater precision in a bloodless field that the tourniquet is advised, and every effort should be made to avoid post-operative hæmatoma, by picking up all vessels *before* division as the operation proceeds, by ligating them, and by firmly applying an adequate quantity of wool in the dressing, while the limb is held elevated. Injury to the nerves of the arm by a tourniquet is avoidable by the use of the pneumatic type of apparatus. The length of time that a tourniquet can be left in place is a constant worry to the operator. It is impossible to be dogmatic as to how long it is safe to keep pressure on the vessels and maintain a bloodless limb. Further, no general rule can be made on the matter. Obviously it is impossible to state that a tourniquet should be used for one operation and not for another, as the speed of each operator varies greatly. The removal of a tourniquet during an operation is most unsatisfactory as this usually causes displacement of towels, the liability of soiling the operation area, and a considerable flow of blood into the wound. Hence, if it is known that an operation will be a long one, it is better to start without a tourniquet; should an operation be started under a tourniquet and occupy a longer time than anticipated, it will be safer to remove the tourniquet, in spite of the disadvantages, than to risk the very serious consequences that may occur if this is not done.

The incision for the operation on any joint should be planned so that an adequate exposure of the joint can be obtained and so that it can be enlarged if necessary. It should be so placed as to afford ready exposure of the intermuscular planes or of the space between tendons. Obviously, vessels and nerves are to be avoided. If an incision has to

be made near the course of a nerve, it is advisable to expose the nerve along a sufficient length of its course to render it visible if necessary during the operation. When this has been carried out, the assistant is told that he must keep a constant watch on it and retract it with care, so as not to bruise it.

When the operation aims at fixation of a joint, the care of *muscles* and *tendons* is not of the same importance as when the object is to improve movement. In all operations, division of muscle is likely to cause bleeding and should therefore be avoided. Whenever possible the approach to the joint should be in intermuscular planes. When insufficient exposure of the joint is obtained by such a route, it may be necessary to separate the origin or insertion of muscles. It is usually advantageous to remove them from the bone with a thin osteotome, so that a thin flake of bone is left attached to the muscle or tendon (e.g. an epicondyle of the humerus). This facilitates reposition and injures the muscle less, so that the muscle functions sooner and more efficiently. The capsule of the joint should be opened in the long axis of the limb, and usually closely in front of or behind a lateral ligament. If it is necessary to remove *the attachment of the capsule completely from* one bone, this is best done with a broad periosteal elevator, after the joint has been opened (e.g. anterior attachment of the capsule of the elbow joint from the humerus). The capsule should not be divided transversely.

ARTHROTOMY

Arthrotomy, indicating the opening of a joint, is a term little used, although the operation is so frequently carried out. The name of the type of operation or of its purpose is more often employed.

The indications for arthrotomy are:

(1) In infective conditions: (*a*) for diagnostic purposes; and (*b*) for drainage.

(2) For removal of foreign and loose bodies from a joint.

(3) Following trauma: (*a*) fractures into joints; (*b*) unreduced dislocations and fracture-dislocations; and (*c*) mobilising a stiff joint.

(4) In disease of the articular cartilage and of the ends of bones.

The skin incision should be placed over the area where the capsule *of the joint is most superficial. Longitudinal incisions should* be employed. The incision should be as small as possible, as a scar in synovial membrane and capsule tends to prolonged effusion. In closing wounds of joints, accurate suture of synovial membrane, with the edges turned out, is advised. Drainage-tubes should not be placed in the joint. Firm bandaging over an ample quantity of wool is necessary.

EXCISION

The classic operation consists in opening a joint, resecting the articular ends of the bone, and removing the capsule and synovial membrane, this being followed by closure of the wound. In most cases the operation has been carried out to remove disease and provide a movable joint. A "text-book description" for excision of most joints of the body exists, but the operations so described are seldom suitable for clinical conditions, owing to the irregularity of the spread of the disease or to deformity from injury. Often removal of a part of a joint will produce an equally efficient result. Some excisions are followed by an ankylosis (e.g. of the knee) which is advantageous, whereas others produce flail joints. This type of operation is not considered at the present time suitable or necessary for tuberculous disease. In the case of post-traumatic lesions, types of arthroplasty now replace most of the formal excisions. Excision of the elbow joint is recognised as a useful operation. Excision should not be practised as an emergency operation after accidents involving joints.

ARTHRODESIS

Arthrodesis is an operation performed to produce fixation of a joint—that is, ankylosis. The latter may be fibrous or bony. Fibrous ankylosis is usually painful and the position of fixation liable to alter. Hence, any operation of the arthrodesis type should be planned to produce bony ankylosis and to put the joint in the best position for function.

There are two methods of performing arthrodesis which are called *intra-* and *extra-*articular arthrodesis; sometimes the two are combined. The first method consists in removal of joint tissue until two bony surfaces can be placed in apposition so that bony union will occur. In the simplest cases this will necessitate removing the articular cartilage from the ends of the bones; whereas in more complicated cases it may be advisable to remove synovial membrane, articular cartilage, and areas of diseased bone. Sometimes the bony surfaces will be kept in contact by the use of pegs of bone, screws or nails, or the inlay of a bone graft taken from another area of the body.

Extra-articular arthrodesis consists in the fixation of the joint by bone without opening the joint. It is carried out by the use of a bone graft obtained from the neighbourhood of the joint or from another part of the body. For instance, a graft from ilium or tibia may be employed to fix the hip joint, the graft uniting the great trochanter to

the ilium. Arthrodesis of a number of joints at the same time is employed in the foot for flail foot.

Joint fixation by fascial transplantation or transposition of tendons is seldom satisfactory; likewise, there are few advocates of such methods as the driving of pegs, pins or screws through the articular surfaces of two bones from without, as a means of producing ankylosis of the joint without exposing the joint.

The principal indications for arthrodesis are: (1) Cases of flail joint due to muscular paralysis or deficiency sufficient to limit a useful function of the joint; (2) certain cases of tuberculosis of joints; (3) cases of infective or toxic arthritis, including osteo-arthritis, particularly when the joint is quiescent and there is a fibrous and painful ankylosis; and (4) subsequent to trauma when a fracture or fracture-dislocation has produced a painful joint.

The indications for this operation are referred to in greater detail subsequently, when discussing particular joints.

Before considering the merits of intra- and extra-articular arthrodesis, it is advisable to stress the importance of a joint being ankylosed in what is popularly termed "*the best position.*" This is not only the position in which the joint is placed when it is arthrodesed by operation, but is the position which should be aimed at whenever the joint is treated. When treatment is being carried out for a joint lesion, of a type such as may lead to ankylosis, it is advisable to place the limb in such a position that, should ankylosis occur, the limb will be in the most useful position for function.

(*a*) *Shoulder joint;* in children—90 degrees abduction; in adults—75 degrees abduction. In both cases, the elbow should be 30 degrees in front of the body plane, i.e. a line drawn through the middle of the body from shoulder tip to shoulder tip.

(*b*) *Elbow joint;* the forearm should be flexed 90 degrees on the arm and midway between supination and pronation. On the rare occasions when both elbows are ankylosed, the most useful position is for the right to be flexed at about 100 degrees and the left at about 75 degrees.

(*c*) *Wrist joint;* dorsiflexed to 45 degrees.

(*d*) *Fingers;* the terminal interphalangeal joint at 150 degrees, i.e. 30 degrees from fully extended.

(*e*) *Hip joint;* flexion to not more than 30 degrees, abduction 20 degrees, and slight external rotation.

(*f*) *Knee joint;* fully extended with the foot square.

(*g*) *Ankle joint;* the foot should be placed at a right angle to the leg.

(*h*) *Foot;* when multiple arthrodeses are carried out, the foot should be displaced backwards below the astragalus.

(*i*) *Interphalangeal joints* of toes should be fixed extended or slightly flexed.

From the remarks on the indications for arthrodesis and from studying the suitable positions in which to fix joints, it will be realised that every arthrodesis is carried out to *fix the joint in a correct position.* Whereas some types of arthrodesis are performed to help to cure disease, or a painful condition of a joint, others aim at correcting deformity. These may be combined. It is essential to consider the merits of intra- and extra-articular arthrodesis and to judge when either is a suitable operation.

By *intra-articular arthrodesis,* it may be possible to eradicate all disease (tubercle of the knee joint); to remove the articular cartilage to ensure bony union (shoulder in muscular paralysis); to convert fibrous into bony ankylosis (ankle joint); and to correct deformity and eradicate articular changes (osteo-arthritis of the hip joint with deformity). Shortening of the limb follows this procedure; it will be no disadvantage in the upper limb, and usually not in the lower limb, except when carried out in children so as to interrupt the growth of the bone. In some joints it is impossible to eradicate all the disease while performing the operation, so that the disease is likely to continue, often more severely than before operation was undertaken. This applies particularly to the hip. Likewise, if intra-articular arthrodesis is carried out when the disease is thought to be quiescent but is in reality still active, a recrudescence is likely to occur and produce a worse condition than was already present. The severity of the operation on the hip, combined with the fact that bony union has not always been obtained, leads operators to employ other methods.

By *extra-articular arthrodesis* it is possible to fix without opening the affected joint. It is suitable in certain cases of tuberculosis either at the commencement of the disease or when it is quiescent (sacro-iliac joint and hip joint); it is equally suitable in cases of fibrous union when an intra-articular arthrodesis will prove an extensive operation, particularly when it is feared there might be a recrudescence of the infective process. One type of extra-articular arthrodesis necessitates opening the joint; for instance, in one operation on the hip joint the graft is laid directly along the upper surface of the neck of the femur; such an operation would be suitable for osteo-arthritis of the hip joint but not for tubercle. As a general rule, a bone graft is not placed through a joint unless the articular cartilage has been removed,

as the graft is liable to absorb in the joint space; but this operation is performed with success by a graft across the ankle joint through the fibula, astragalus and tibia, when it can be planned so that the graft never actually forms a bridge.

Extra-articular arthrodesis is eminently suitable for certain cases of tubercle, particularly when the graft is implanted well away from the disease. Experience has shown how successful grafting of the spine is in cases of disease of the vertebræ in adults. Surgeons are tending to employ it for the hip joint, but there is no unanimous opinion as to the right time at which it should be undertaken, particularly in the hip and sacro-iliac joints. Tubercle of the hip joint in children and adults usually destroys a good deal of tissue even when the best treatment is carried out by general methods and efficient local treatment. The majority of cases treated without operation have a fibrous union at the end of their treatment; this is painful at some time later in life, and the joint tends to get into a position of flexion and adduction. Consequently, the present tendency is to advise early extra-articular arthrodesis of the hip, so that extra-articular bony union is assured; as the result of the operation the disease tends to spread less and to heal more quickly, deformity is prevented, and bony union is obtained. If the operation is delayed until the disease is quiescent, deformity may have arisen and shortening have occurred; hence, arthrodesis may be considered necessary in order to produce a painless joint and deformity may have to be corrected as well by an osteotomy; two operations of this nature may not be advisable when there is any doubt as to whether the disease is active.

It is probably fair to state that: (1) Extra-articular arthrodesis of the hip in an early stage of the disease has many advocates; (2) an arthrodesis of the knee joint for tubercle in adults is the recognised procedure as soon as the condition is confirmed by biopsy; and (3) that some form of arthrodesis, preferably extra-articular, is advocated in all cases of joint tubercle when they are quiescent, provided no sinus exists.

ARTHROPLASTY

Arthroplasty is an operation designed to produce movement at a joint —in fact, an artificial pseudarthrosis. The *principles* of the operation consist of: (1) The removal of bone and soft tissue, if any, interposed between the original joint surfaces; and (2) the prevention of union between the opposing ends of the bones.

Success of the operation depends on: (1) The removal of the correct amount of bone and the shaping of the ends of the bone which will

take part in the new joint; (2) the separation of the ends of the bones and the employment of some method to prevent their union; (3) the efficiency of the muscles around the joint; and (4) careful after-treatment.

Details of technique.

(1) The bone. When bony ankylosis exists, it is essential to divide this and to reshape the ends of the bones. When fibrous union exists, not only must the ends of the bones be shaped, but the interposing soft tissue must be excised. The quantity of bone that should be removed is a matter of controversy and must depend on the type of joint which one wishes to make. The common error is the removal of too small a quantity of bone. In shaping the ends of the bones, both stability and function must be considered; for instance, in the case of the elbow, every effort should be made to fit the joint surfaces accurately, and only sufficient bone should be removed to give free motion. The olecranon and sigmoid fossa should be preserved, or, if that is not possible, a new olecranon must be made. In the case of the hip joint, the plastic work is carried out on the head of the femur rather than on the acetabulum; but in the knee, the femur and tibia are both shaped. In this joint, stability is essential for weight-bearing, and is most easily obtained by cutting the lower end of the femur into a V-shape with an angle of 120 degrees in the angle in the V.

(2) The prevention of bony union is carried out by extension on the limb after the operation, and by applying Horsley's wax to the raw bony surfaces, or by the interposition of a flap of soft tissue. Wax is little used in this country for this purpose, and there is a divergence of opinion as to the value of an interposed flap. At one time it was thought that such a flap should consist of two layers and have a pedicle. It has been proved that a pedicle to a flap is of no advantage and that a flap of one layer is certainly as efficient as a double one. The next question is whether the flap should consist of fascia or of fascia and fat. Fat probably absorbs quickly, but fascia will live after transplantation, although the edges may necrose. The free flap is usually taken from the outer side of the thigh. Some surgeons rely on separation of the joint surfaces alone and do not use the fascial flap. When the latter is used, it should cover one bone snugly and thoroughly and should be fixed in position by a few interrupted catgut sutures. This is a particularly suitable covering for the lower end of the humerus and the head of the femur.

(3) Muscles. Muscular efficiency of any joint requiring this operation is below normal because the muscles will not have been in action

while the joint has been ankylosed or had great limitation of movement; but if there has been no nerve paralysis and the muscles are of a reasonable shape and size, their efficiency will return with after-treatment.

(4) The *after-treatment* consists in keeping the part at rest with extension. The length of time this is necessary will depend on the joint: the larger the joint the longer it is kept in extension. If voluntary movement can be started two weeks after the operation, immobilisation should certainly be continued, although a small amount of movement and muscle re-education is carried out daily. The *increase in the movement must be determined by the functional development,* and no passive movements should be employed. The aim should be for the patient to be able to work hard at moving his elbow in three weeks and for him to be bearing weight on the knee in six weeks and on the hip in four, but full weight-bearing will not be possible for ten to twelve weeks, and in the latter two cases a caliper *will help the patient considerably. Sudden increase of movement should not be* looked for. If the ends of the bones have a mottled appearance in the skiagrams six or eight weeks after the operation, the bones are likely to be soft, and rapid progress must not be expected. This appearance is an indication to limit weight-bearing but to encourage muscle training and voluntary movement.

The operation of arthroplasty is suitable in certain joints under favourable circumstances when the ankylosis has resulted from: (1) Trauma causing injury to joint surfaces and periosteum, particularly after severe fractures and fracture-dislocations; (2) acute arthritis due to staphylococcus, streptococcus and gonococcus, when the infection has been localised to an arthritis and the erosion has not been deep; or (3) certain cases of chronic arthritis, such as osteo-arthritis of the hip joint.

Mobilisation of a joint is contra-indicated when: (1) It is known that the infective process is still active; (2) the ankylosis was due to tuberculosis, in which case the risk of "lighting up" old infection is well recognised and, although successful arthroplasty has been accomplished, the risk is great; (3) the soft tissues are bound down to the bones by extensive scar tissue; (4) muscular weakness around the joint is extreme; and (5) the shafts of the bones near the joints are scarred by old infection and are either sclerosed or greatly rarefied.

Arthroplasty in children is seldom required and should be employed *with great caution.*

The favourable circumstances for mobilisation of a joint are: (1) Age between twenty and forty; (2) status of the patient—one who will co-operate in post-operative treatment and is intelligent; (3) general fitness of the patient and complete freedom from local or toxic infection; and (4) absence of scar tissue, particularly involving muscles around the joint.

Success of arthroplasty is greatest in the elbow, hip joint, and jaw. These joints are suitable because the articulation can be remodelled so as to be stable. Experience is showing that the keen joint is moderately suitable. Finger joints are seldom good joints for arthroplasty, as the tendons around the joint are usually badly scarred. The shoulder seldom needs mobilising, and arthrodesis of the wrist in dorsiflexion is satisfying. Although arthroplasty of the ankle has been performed, it is not necessarily painless, wherefore arthrodesis is to be preferred.

Operations on Individual Joints

TEMPORO-MANDIBULAR JOINT

Operation on this joint is required in cases of: (1) "Clicking jaw" or other symptoms indicating a lesion of the intra-articular disc of fibro-cartilage; (2) arthritis; and (3) ankylosis. (See also page 5121.)

The operation for the first condition consists in the removal of the disc. When *arthritis is painful and causing limitation of movement, the* condyle can be removed. In cases of ankylosis the condyle can be resected or an arthroplastic operation can be carried out, a flap of fascia lata or of temporal muscle being sutured over the neck after removal of the condyle.

Esmarch's operation on the horizontal ramus is suitable when the fixation of the jaw is due to cicatrices of the soft parts.

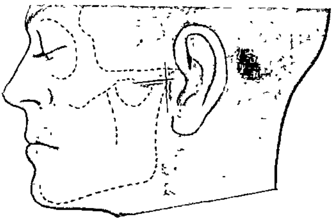

Fig. 2326.—Diagram showing the alternative incisions for exposure of the temporo-mandibular joint. The vertical incision is to be preferred, although the two may be combined.

Exposure of the joint. There is a choice of two incisions, either of which is probably efficient. The easiest incision is a vertical one in front of the ear parallel to the posterior border of the ascending ramus, which should extend from the upper border of the zygoma for a little more than one inch downwards. The alternative incision is along the lower border of the zygoma on a level with the tragus; the two incisions can be combined (fig. 2326). It is advisable to pick up the superficial

temporal vessels and to tie them, but branches of the facial nerve and the upper border of the parotid gland should be displaced downwards; the fibres of the masseter muscle are divided with a knife from the zygoma, and separated with a periosteal elevator. The capsule of the joint is then exposed and a vertical incision is made through it, exposing the neck of the mandible. If the operation is carried out to remove the fibro-cartilage, the incision is carried up through the capsule; this is drawn aside, and the cartilage is grasped in a pair of small artery forceps, drawn downwards, and separated from any attachment with a tenotomy knife. A stitch is put into the capsule, the masseter muscle replaced, and the wound closed.

When the operation of removal of the condyle is carried out, it is important to remove a considerable portion of bone, and the external pterygoid muscle must be separated from the neck. The neck is divided with a pair of small bone-cutting forceps. It will be known beforehand from the X-ray pictures whether the condyle is of normal shape or considerably destroyed. This information is very important as it is not easy to remove a deformed ankylosed condyle. If fascia is interposed, this must be stitched round the stump. Movement is commenced on the following day. If it should be necessary to do this operation on both condyles, a wedge should be kept between the teeth for two to three weeks and should only be removed for cleansing of the mouth, feeding, and movement. It is probable that little advantage is gained by using a fascial flap.

It is most important not to injure the parotid gland, or a parotid *fistula may form. A partial facial palsy occurs in a proportion of cases* but is only of a transient nature.

STERNO-CLAVICULAR JOINT

Operation on this joint is required in some cases of unreduced dislocation and of recurrent forward dislocation. As the joint comes into action when the arm is abducted beyond a right angle, fixation of the joint may impair the movements of the shoulder girdle. This is more likely to be the case if the joint is fixed owing to former infection (a rare condition) than in an unreduced dislocation. In either case it is probably advantageous to excise the inner end of the clavicle if the patient has a definite disability. In treating recurrent forward dislocation, the operator's ingenuity must come into play, as a buttress must be formed to prevent the clavicle from sliding forward.

ACROMIO-CLAVICULAR JOINT

The common injury to this joint is an upward dislocation of the clavicle. Such a condition may persist if the primary treatment has failed or if there have been repeated injuries. The superior acromio-clavicular ligament has usually been torn and the conoid and trapezoid ligaments stretched or detached. When considering operative treatment, it is important to determine whether the

disability is sufficient to warrant operative treatment. If the latter is undertaken, an effort should be made to reconstruct the parts rather than to fuse the clavicle to the acromion (fig. 2327). The operation will consist in exposing the acromio-clavicular joint and making new ligaments from fascia, probably fixing the clavicle to the acromion by a band of fascia passed horizontally through drill holes in both bones. In addition, it will often be necessary to replace the useless conoid and trapezoid ligaments by fascia passed round or through the clavicle to the coracoid process.

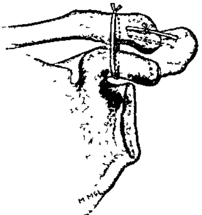

Fig 2327.—Diagrammatic representation of *fixation of clavicle to acromion and coracoid process by fascia lata or kangaroo tendon.*

SHOULDER JOINT

Arthrotomy. The opening of the shoulder joint is necessary in cases of: (1) Infective arthritis; (2) fracture-dislocations and some cases of unreduced dislocations; and (3) loose bodies in the joint.

The usual procedure is to open the joint from the front in cases of infective arthritis, and this is always done unless there is a definite swelling posteriorly. Counter-incisions posteriorly or at the apex of the axilla are sometimes necessary and helpful. If the latter is used, the arm must be drawn upwards above the head while the counter-incision is made. Although this incision provides good drainage, the dressing is not easy, and discharge over the axilla is liable to cause infection of the hair follicles. If the infection has arisen as a complication of osteomyelitis of the upper end of the shaft of the humerus, the bone should be approached from the postero-lateral aspect, and if drainage of the joint is considered necessary, this will be carried out through the posterior part of the capsule.

Arthrotomy by the anterior route is the method employed for the other conditions. A small sand-bag is placed behind the shoulder and the arm is slightly abducted. An incision is made from the lower border of the clavicle half-way between the coracoid and acromion processes, extending downwards in the line of the deltoid fibres. The deltoid muscle is split about 1 inch lateral to its inner border. There will be some hæmorrhage which is easily controlled. The muscle-fibres are retracted, exposing the bicipital groove if the arm is externally rotated.

Retraction of the upper part of the muscle will expose the joint. Some surgeons, however, prefer to retract the whole deltoid muscle without splitting it.

In the case of removal of *loose bodies,* the capsule will be split from above downwards and closed after removal of the bodies (fig. 2328).

In the case of *fracture-dislocation,* it will be necessary to decide if the head can be fixed on to the shaft and the dislocation reduced, or whether

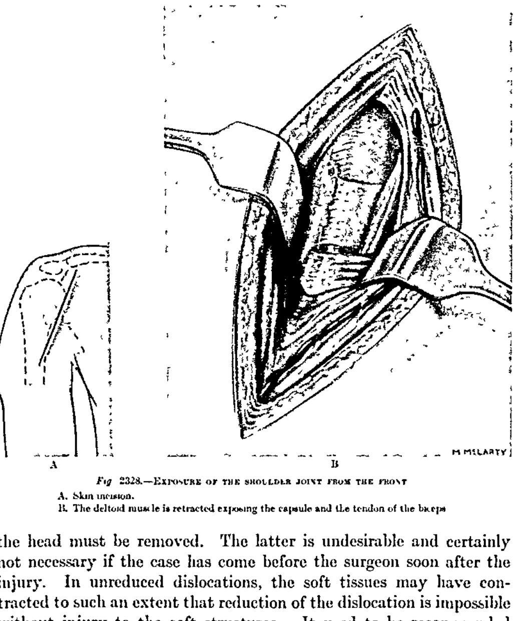

Fig 2328.—Exposure of the shoulder joint from the front

A. Skin incision.

B. The deltoid muscle is retracted exposing the capsule and the tendon of the biceps

the head must be removed. The latter is undesirable and certainly not necessary if the case has come before the surgeon soon after the injury. In unreduced dislocations, the soft tissues may have contracted to such an extent that reduction of the dislocation is impossible without injury to the soft structures. It used to be recommended that the head of the humerus should be excised, but a stronger arm will be obtained if reduction can be carried out, although full movements may not be obtained subsequently. After the operative procedure has

been carried out, the capsule is closed with interrupted stitches, the deltoid brought back, and the skin closed. After any one of these operations, the arm should be fixed in abduction prior to physical treatment which will consist of faradism to the deltoid, active movements. etc.

Arthrodesis. Indications: (1) Flail shoulder; (2) permanent deltoid paralysis; and (3) some cases of tuberculosis of the shoulder joint.

The operation for the first two conditions is intra-articular or combined intra- and extra-articular arthrodesis. Extra-articular arthrodesis is suitable for cases of tuberculosis, particularly when the inner portion of the head is mostly affected and tends to sink inwards. Whether this should be practised at the commencement of the disease or after general treatment and immobilisation has been carried out is a debatable point.

Intra-articular Arthrodesis. This is usually required in cases of infantile paralysis producing flail shoulder; the best permanent results are obtained if the operation is delayed until the age of puberty.

A sand-bag is placed behind the shoulder, an incision is made from just above the tip of the acromion downwards in the line of the deltoid fibres. The muscle will be thin, and is split in the line of its fibres; the capsule is divided freely and the biceps tendon preserved. The head of the humerus is brought out into the wound. The articular cartilage is removed, and the head shaped so that it will fit into the small glenoid fossa. This is carried out most easily by entirely removing a portion of the front and back and then taking the articular cartilage only off the central portion, which can be shaped to fit the glenoid subsequently. During the shaping of the head the operator must realise that in a child the arm will be fixed in a position of 90 degrees abduction and 30 degrees external rotation, with the elbow in front of the body line. The abduction should be about 70 degrees in an adult. The articular cartilage is then removed from the glenoid and the head fitted against it. The wound is closed, and a large plaster is applied round the trunk and over both shoulders and the arm of the affected side (see fig. 2331). The limb must be put in the position already described, with the elbow flexed to about a right angle and the wrist dorsiflexed. A window can be cut above the shoulder and over the wound for removal of the stitches. The plaster should remain in place for three months. Subsequently, movement of the limb is obtained by the action of the muscles on the scapula.

Additional aids to the fixation of the humerus to the scapula can be obtained by: (1) Driving a peg of beef bone or a bone graft through the head into the glenoid; and (2) separating the greater tuberosity

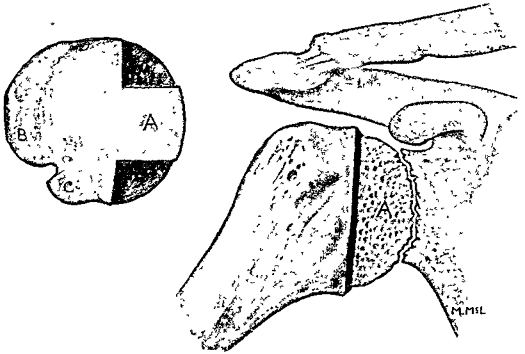

Fig. 2329.—Arthrodesis of the shoulder.

Left hand fig.—The trimming of the head of the humerus has been commenced by removal of two lateral portions, leaving the central piece A, which is to fit into the glenoid cavity. A is still covered by articular cartilage; B, great tuberosity; C, small tuberosity.

Right-hand fig.—Head of humerus and glenoid in apposition after removal of the articular cartilage from both.

Fig. 2330.—Combined intra- and extra-articular arthrodesis of shoulder. The great tuberosity has been elevated and the acromion process, after being bared on its surfaces, placed between shaft and tuberosity. The clavicle and spine of the scapula have been divided to allow the acromion to drop.

from above downwards, leaving it hinged below, and by cutting through the acromion process and, after removing the soft tissues attached to it, inserting it between the greater tuberosity and the bone (see fig. 2330).

Extra-articular Arthrodesis. This is carried out through a similar incision prolonged upwards, and by inserting the acromion, after its

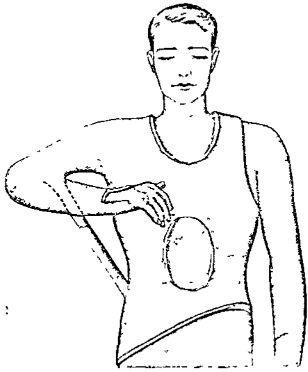

Fig 2331.—Shows plaster applied to trunk and upper limb after arthrodesis of the shoulder.

surfaces have been freshened, into a groove between the greater tuberosity and the humerus in the manner already mentioned. This is facilitated by dividing the clavicle 1½ inches from its outer end and the spine of the scapula at a similar distance (see fig. 2330).

Recurrent Dislocation of the Shoulder

When repeated dislocation of the shoulder occurs with little trauma, operative treatment offers complete cure to a large percentage of patients. Epilepsy is no contra-indication. A variety of operations are still carried out, all of which have definitely taken the place of arthrodesis, as full movement should be obtained by any one of them. Most of those in use to-day are intended to prevent the recurrence of the dislocation by altering the normal periarticular structures and yet allowing full movement. The pathology of the condition, as to whether the bone, capsule or muscle tissue is the primary lesion, is not considered in any

of these operations except in that of Bankart. Yet a high percentage of good results is reported by the advocates of each.

The operations are of two types:

(1) Those designed to prevent recurrence by the introduction of a sling; (*a*) Of muscle. Clairmont's operation consists in separating a strip of the posterior border of the deltoid, carrying it forward through the quadrilateral space, and fixing it to the subscapularis tendon. This operation is theoretically suitable in cases of dislocation when the primary displacement is downward; (*b*) Of tendon. Nicola's operation (*Jl. Bone and Joint Surgery*, 1934, XVI, 663) consists in passing the tendon of the long head of the biceps through the head of the bone. The bicipital groove is exposed by an incision through the anterior part of the deltoid. The biceps tendon is exposed up to the joint by dividing the transverse humeral ligament which keeps the tendon in the groove. The tendon is divided an inch below the lower border of the ligament. With a $\frac{1}{4}$-inch drill a hole is made, starting in the bicipital groove 1 inch distal to the small tuberosity and passing upwards in the line of the tendon, but coming out through the articular surface a half to three-quarters of an inch from the edge of the articular surface. The tendon is passed through this from above downwards and sutured to the distal portion; the transverse humeral ligament is sutured back and also stitched to the biceps tendon after abducting the arm. Fixation with the arm beside the chest wall is employed for two weeks.

(2) Operations on the joint itself, or combined with some other procedure: (*a*) Plication of the capsule alone is seldom curative and is not recommended; (*b*) Repair of the glenoid ligament alone or with plication of the capsule and shortening of the subscapularis tendon.

Bankart advocates the following operation as he considers that when the dislocation occurs " the head shears off the fibrous capsule of the joint from its attachment to the fibro-cartilaginous glenoid ligament." A sand-bag is placed behind the scapula, and the anterior incision for exposing the shoulder joint is employed. The coracoid process is divided with an osteotome and drawn downwards with the muscles attached to it. The tendon of the subscapularis is defined, divided from the humerus, and drawn inwards. The anterior aspect of the shoulder joint is now exposed. The glenoid ligament may appear as a free edge, and a band of fibrous tissue forming the border of the torn capsule may be seen running from above downwards; if it appears flat, it should be elevated and kept in this position with a small wedge of bone. The fibrous capsule should then be fixed to the bone

along the anterior margin of the glenoid. The subscapularis tendon and detached coracoid process are re-attached and the wound closed. The arm is kept at rest for four weeks before active and passive movements are commenced.

(c) By the formation of a bony buttress in front of the joint and

by shortening of the subscapularis tendon, with plication of the capsule if this is loose.

The coracoid process, the front of the joint, and the subscapularis muscle are exposed by separation of the anterior fibres of the deltoid. The coracoid process is split obliquely from before backwards, so that the tendon of the coraco-brachialis and the short head of the biceps can be turned downwards.

The tendon of the subscapularis is divided ½-inch from its insertion. The anterior portion of the capsule is examined and, if lax, plicated. The subscapularis tendon is overlapped and the slack taken up as it is united ; stitches are passed through the aponeurosis of the two pieces of coracoid process, so that the free portion (to which the coraco - brachialis and biceps are attached) will unite to the fixed piece, but tilted downwards so as to form a bony block in front of the joint. After closure of the wound, a large pad of wool is placed in the axilla, the elbow is bent to a right angle, and the arm is fixed in plaster to the side of the thorax for ten weeks. In Oudard's original operation the coracoid was lengthened by insertion of a graft.

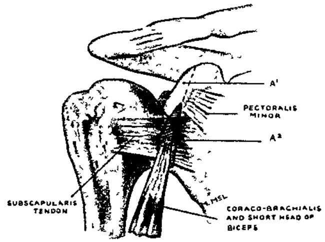

Fig. 2335.—OPERATION FOR RECURRENT DISLOCATION OF THE SHOULDER (*after Oudard*)

A² Indicates the new position of the lateral half of the process.

There is no doubt that successful treatment of this condition has been carried out by each of these methods. In view of the fact that bony, capsular or muscular lesions may be present, it is certain that the routine use of one method is unlikely to be curative in every case, except probably by the employment of Bankart's operation. The sling operations are less in favour at the present time than ten years ago because Clairmont's operation is extensive and failures have been reported. It is suggested that the failures are due to the fact that the success of the operation may depend on the formation of a pad, and that in course of time this pad diminishes in size. Nicola's operation necessitates injury to the joint, and undoubtedly the tendon will absorb. Bankart's operation has produced good results but is difficult,

and it is perhaps questionable whether it
so extensive an operation as this is; it

gently removing the anterior part of the capsule from its attachment to the humerus. Such an approach will make it possible to remove a loose body from the anterior part of the joint or to carry out an operation on the capitellum, or on the head or neck of the radius. The capsule must be closed on the outer side, and the origin of the muscles reattached to the external epicondyle. A line of sutures is placed in the divided aponeurosis of the extensor muscles and the wound closed. The

limb is placed in a light plaster with the elbow at a right angle and the forearm supinated. It is kept at rest for three weeks before active movements are commenced. Massage must not be employed after this operation.

Excision of the elbow joint. This operation consists in the removal of: (1) The lower end of the humerus by a transverse line drawn through the middle of the internal epicondyle; and (2) the head and neck of the radius and of the upper end of the ulna at the level of the neck of the radius. The diseased tissue (if any) is dissected out, but every endeavour is made to preserve the insertion of the triceps and the external lateral ligament.

The operation is indicated: (1) For tuberculosis of the elbow joint when conservative methods are not leading to a successful issue; and (2) in certain cases of suppurative arthritis following compound comminuted fractures involving the joint. This operation can be carried out when sinuses are present, and the wound be drained subsequently, whereas an arthroplasty is not advocated in the presence of infection.

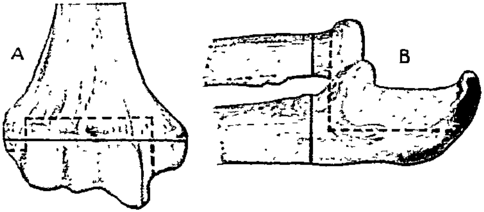

Fig 2337.—The bones of the elbow joint showing.
A. Lines of section of the bones in excision (continuous lines).
B. Lines of section in arthroplasty (dotted lines).

The operation through a lateral incision, as described by Kocher, is the one usually practised. Flexion and extension are generally satisfactory, but lateral instability often occurs after excisions of the elbow.

The *after-treatment* consists in keeping the joint at right angles for two weeks; from that time movement is encouraged, but the arm must be kept at rest between the exercises. It is probably advantageous to keep it in different positions of flexion and extension for four to five weeks before discarding all splinting. Electrical treatment and massage to strengthen the muscles will help to prevent lateral instability.

Arthroplasty. Indications: (1) *Traumatic conditions*—(*a*) Certain comminuted fractures of the elbow joint; (*b*) bony or fibrous union following fractures involving the joint. In adults, when a simple comminuted fracture of the lower end of the humerus has injured the articular surface to such an extent that good function of the joint is unlikely to occur, an arthroplasty carried out within ten days of the injury is a sound procedure. In fact, the result is likely to be better than when the operation is carried out late owing to irregular bone formation, contraction of the capsule, and wasting of the muscles which are such frequent sequelæ of severe injuries to the elbow joint.

(2) *Ankylosis following infective arthritis.* Arthroplasty is seldom advisable in any case of tuberculosis of the joint. It is important to

delay this operative procedure until the surgeon is satisfied that no infective process is present or likely to be brought to light by any operative procedure. Good results are reported when there has been bony ankylosis, and undoubtedly best function follows those operations which are carried out when the bones have been little damaged by an infective arthritis.

This operation to regain movement is probably of little value for a labouring man, who can do moderately hard work with an ankylosed elbow, provided it is not painful. It is recognised that fibrous union of the elbow is not as painful a condition as it is in the knee or ankle joint. However, a flail elbow is a particularly serious disability for the workman, and is found to arise as the result of gross injury to the bones or of imperfect technique in carrying out an excision.

Technique. The technical details of an arthroplasty cannot be standardised, as each case must be treated on its merits. A pneumatic

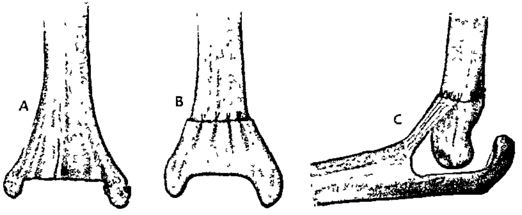

Fig. 2338.—Arthroplasty of the elbow joint.

tourniquet is used. The skin incision must depend on the position of any scar tissue. It is essential that it should be sufficiently long to give free access to the joint. A posterior incision 7 inches in length, with the centre over the tip of the olecranon, provides good access. As there are certain advantages in the incision not being directly over a bony point, an incision of similar length can be employed on the lateral side of the triceps tendon and carried down between the radius and ulna. The triceps aponeurosis is divided at the joint level, and the tendon and a thin slice of olecranon, including the tip, are removed with an osteotome and retracted upwards. The ulnar nerve is isolated and retracted, and the lower end of the humerus is cleared. As it is usually necessary to

remove the lower end of the humerus above the epicondyles, it is advisable now to remove the epicondyles and their muscle attachments with a thin osteotome. If there is bony union, this must be broken down by means of a gouge. If it is a case of fresh fracture, loose fragments of bone are removed. If there is fibrous union, the joint is broken open. The lower end of the humerus is then brought out into the wound, care being taken that the periosteum is not stripped up. Before dealing with this, the radius and ulna are examined. These should be interfered with as little as possible, but if the head of the radius is devoid of articular cartilage, it is better to remove the head and a small portion of the neck unless the surgeon has decided to do this at a second operation. With regard to the ulna, it is essential to leave or remodel the great sigmoid fossa. If articular cartilage no longer exists, it will be necessary to remodel this, but every endeavour should be made to preserve the olecranon process. The loss of the coronoid process does not interfere with stability to such an extent. The lower end of the humerus is now fashioned by removal of the old articular surfaces up to the level of the olecranon fossa. Some surgeons aim at endeavouring to reshape the bone into what it was before, but the majority prefer to cut the bone just distal to the olecranon fossa so that the divided surface is quadrilateral. A rasp or file is now used over the raw bony areas. The humerus should then be placed in the sigmoid fossa to test the fit.

The next step is to cover the lower end of the humerus with a flap. This is not employed when the operation is being carried out for a recent fracture, but by most surgeons for other conditions. The flap should consist of a free fascial flap removed from the thigh, or of a musculo-aponeurotic flap removed from the deep surface of the triceps. In either case the flap is sutured round the lower end of the humerus and preferably attached at one or two places to the front of capsule of the joint. Care is taken that the forearm bones are in correct relationship to the humerus, and the addition of a few stitches from the capsule to the fascial flap will help to prevent the humerus from losing its correct relationship to the ulna. The epicondyles are fixed back to the humerus, the olecranon and triceps aponeurosis are sutured into place, and the wound is closed. After application of dressings, the arm is put in plaster, flexed just above a right angle in full supination. The stitches are removed in two weeks and a posterior plaster trough made; movement is then commenced, future treatment being as for other cases of arthroplasty.

Operations on the head and neck of the radius are described in Chapter IV of this section.

INFERIOR RADIO-ULNAR JOINT

Ankylosis of this joint is treated by an operation on the lines devised by Baldwin. An incision is made over the lower part of the ulna between the flexor and extensor carpi ulnaris, the ulna is exposed, and a point $1\frac{1}{2}$ inches from the head of the ulna is located. Half an inch above and below this point the periosteum is incised in a circular fashion, and the ulna is then cut through in two places so as to remove less than 1 inch with the periosteal sheath. A small portion of the muscular tissue in the neighbourhood is stitched round the proximal end of the ulna, and the wound is closed. The part is kept at rest for three weeks. Good results are obtained as union does not occur between the two ends of the ulna. (*Orthopædic Surgery of Injuries*, R. Jones. Oxf. Med. Publs., 1921.)

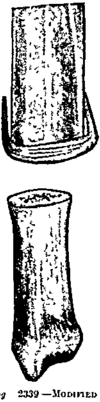

Fig. 2339.—Modified Baldwin's operation. A cylindrical portion of the ulna has been excised above the pronator quadratus. A flap of muscle has been turned over the proximal end.

WRIST

Arthrotomy for purposes of drainage is seldom required. The wrist joint is opened for removal of part or the whole of the scaphoid and for unreduced dislocation of the semilunar bone. The operation is described in the chapter on fractures (see page 4444).

The operation of excision of the wrist joint was at one time carried out in cases of tuberculosis, but success of this operation seldom equals the conservative treatment, so that operative measures for this condition are limited to removal of sequestra only; this is seldom required except when sinuses have persisted for some time.

When ankylosis is present in a bad position or when there is lipping of bone on the back of the radius and carpal bones so as to limit dorsiflexion, operative treatment is indicated. The operation of arthrodesis is advisable for the former; the bony lipping can be removed alone, or in more severe cases arthrodesis also can be performed. Arthroplasty of this joint is not recommended; its success will enable natural movement as well as flexion to be carried out, but in the cases reported, the degree of dorsiflexion which is so valuable has not always been maintained.

Technique of Arthrodesis. A pneumatic tourniquet is employed round the arm. An incision—4 to 5 inches long, with its centre over the wrist joint, is made along the radial side of the extensor proprius indicis.

The veins are clipped and divided, the posterior annular ligament is cut, and the tendons are retracted. The line of the wrist joint is defined, and a chisel inserted so as to divide the lower end of the radius at right angles to the shaft but obliquely from behind forwards. The proximal surfaces of the scaphoid and semilunar bones are removed. The ulna and cuneiform are cut through similarly, so that a wedge of bone is removed with the base at the back and the point of the wedge forward. This will make it possible for the wrist to be dorsiflexed 45 degrees. It

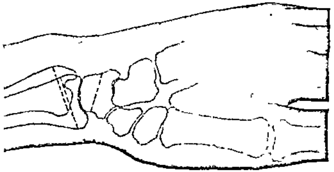

Fig. 2340.—Arthrodesis of the wrist joint. The lines indicate lines of section of the bones to fix the wrist in dorsiflexion.

is important to divide the radius and ulna right through to the front. The bones should fit accurately.

It may be possible to insert one or two catgut sutures to help to hold the bones together before replacing the tendons in their correct position and closing the annular ligament and skin. A plaster is applied which includes the thumb and first phalanges and extends up to the elbow joint, care being taken that the wrist is in the position of dorsiflexion already mentioned. In two weeks the stitches are taken out and a more tightly-fitting plaster is applied. Movement is encouraged in such portions of the fingers as is possible. At the end of ten weeks from the time of operation, the plaster is removed and a skiagram taken to see if bony ankylosis is secure.

METACARPO-PHALANGEAL JOINTS

Operation is required on these joints for open reduction of dislocations when closed reduction has failed. If the operation is carried out soon after injury, it will not be difficult to see what structure is preventing reduction. This can be elevated out of the joint and the dislocation reduced. When a dislocation has been present for some weeks, it is probably best to attempt open reduction on similar lines.

Arthroplasty is sometimes practised for such a condition and for *stiff joints due to other causes*; however, good movement after mobilising this joint is seldom obtained and fibrous union is the usual

sequence. In performing arthroplasty, incision is made to one side of the extensor tendon; the head of the metacarpal bone is preserved as much as possible, the cartilage only being removed, but the base of the phalanx is cut away so as to make a larger joint space. A sheet of fascia from the thigh is fixed round the head of the metacarpal bone and the tissues surrounding the joint are brought together to re-form the posterior part of the capsule. It is essential to apply extension to the finger; this is best carried out by passing a finger-pin and stirrup through the pulp of the finger, and fixing this with tape to a notch in a piece of wire extending beyond the finger distally and attached to a plaster cuff round the wrist as is used in a case of fractured phalanges (see fig. 2391). Finger movements should be commenced two to three weeks after the operation; the extension can be continued for five to six weeks, being removed daily for exercise.

TERMINAL INTERPHALANGEAL JOINT

Arthrodesis of this joint, particularly in the first and second fingers, is useful in unreduced fracture-dislocations which are painful. An incision is made to one side of the joint in a line with the edge of the nail. The joint is exposed, articular cartilage removed with a thin-bladed osteotome, and the bone shaped so that the terminal phalanx is slightly flexed on the second phalanx. It is important that the two pieces of bone should fit snugly; this may be made possible by passing catgut sutures through the periosteum or by shaping the second phalanx to fit into the terminal one. The finger is splinted with a malleable metal splint or light plaster for six weeks, when an X-ray picture is taken to see if union is firm.

SACRO-ILIAC JOINT

The operation of arthrodesis of this joint is performed for sacro-iliac arthritis (sub-acute, particularly after pregnancy, and chronic), and for tuberculosis. Both intra- and extra-articular arthrodesis is practised. The extra-articular operation is obviously suitable for either condition and, although some surgeons practise the intra-articular operation for either condition, it is considered that tuberculosis should be treated by the extra-articular arthrodesis only.

The cases of low backache due to arthritis are usually treated by physical methods—heat, massage, perhaps manipulation and a corset—before resorting to operation, even when X-ray changes show arthritis. Before deciding on an operation, it is most necessary to determine if the signs and symptoms are due to arthritis of the sacro-iliac joint only, to

a similar condition of the lumbar spine, or to both. In the first case, sacro-iliac arthrodesis is indicated; in the second, fusion of the lumbar spine; and in the third, a combination of these two operations.

In the case of tuberculosis of the sacro-iliac joint, conservative treatment by rest on the back in a plaster bed or similar apparatus will form the most important part of the treatment, and there is a divergence of opinion as to whether any operative treatment is advisable. There are three alternative lines of treatment:

(1) Sacro-iliac arthrodesis as soon as the diagnosis is made;

(2) Exposure of the affected area, removal of as much disease as possible, and fixation with a bone graft extending through the area of the disease; or

(3) Arthrodesis at the termination of the conservative treatment when the symptoms, signs and X-ray appearance suggest that the disease is no longer active.

Some surgeons consider that an abscess is not a contra-indication to the operation, but in the presence of sinuses surgery is definitely contra-indicated. Those who favour early operative treatment are influenced by the fact that the disease is recognised as a serious manifestation of tuberculosis and that early steps to allay the condition surgically are likely to cure it more quickly, and, further, to limit or prevent other foci of tubercle appearing elsewhere in the body. Most surgeons are content to treat the condition conservatively only if other foci of tubercle are active. Experience of operative treatment for this condition is still limited. At the present time I consider that the best procedure is to perform an extra-articular arthrodesis at the termination of the conservative treatment.

The extra-articular arthrodesis described by Verrall is practised by a number of British and French surgeons, both for sacro-iliac arthritis (uni- or bi-lateral) and for tuberculosis. The operation necessitates removing a bone graft from the tibia. The results on the whole are gratifying, but absorption of the graft on the medial aspect of the ilium may occur. Those who are familiar with this operation will probably employ it for both conditions in preference to the operation of Smith-Petersen which is intra-articular and therefore, in the author's opinion, not suitable for tuberculosis.

There are obvious advantages in removing the bone graft from the ilium without employing a tibial graft; it is considered that for unilateral sacro-iliac arthritis the operation of Smith-Petersen is the one of choice, but that for unilateral sacro-iliac tuberculosis an extra-articular operation, using a graft from the ilium, is to be preferred.

Extra-articular Arthrodesis. A week prior to any one of these operations, a plaster bed should be made, so that the patient can be placed in it at the end of the operation.

The technique of *Verrall's operation* is as follows (fig. 2341):

The skin incision consists of a semilunar flap with the base downwards, the convexity being over the top of the 5th lumbar spine. Both posterior superior iliac spines are exposed, together with the muscles on the back of the sacrum. The spines are cleared of muscle and aponeurosis, and the spinous process of the sacrum which intervenes between these two is removed with a large pair of bone forceps. A tunnel the size of a little finger is made in each ilium in front of the posterior superior spines. A bone graft of the required size is cut from

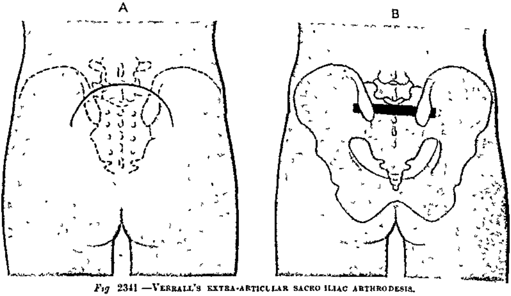

Fig. 2341.—Verrall's extra-articular sacro-iliac arthrodesis.
A. Skin incision.
B. Graft from tibia *in situ*.

the tibia and driven through the ilium deep to the muscles on the back of the sacrum and into the other tunnel. It should lie in contact with the raw area made on the sacrum by the removal of the spinous process.

Intra-articular Arthrodesis of Smith-Petersen. The skin incision consists of a 4-inch incision along the posterior two-thirds of the iliac crest which is continued in a curved fashion round the posterior superior iliac spine and then forwards in the line of the gluteal fibres for 3 inches from the posterior superior iliac spine. The incision is carried right down to the bone (see fig. 2342).

With a broad periosteal elevator the periosteum and overlying muscle are reflected downwards and forwards, commencing along the outer border of the posterior part of the crest of the ilium. This is continued until the sacro-sciatic notch is exposed. The flap is held retracted by the

assistant, while the operator maps out on the bone a rectangular area which he considers to correspond to the sacro-iliac joint. The inferior border of this joint corresponds to a line just above the sacro-sciatic notch and the anterior border to the medial gluteal line. The piece of bone marked out should be approximately $1\frac{1}{2}$ by $1\frac{1}{4}$ inches. With a thin-bladed osteotome this rectangular piece of bone is removed so as to make a window down to the sacro-iliac joint. It should extend

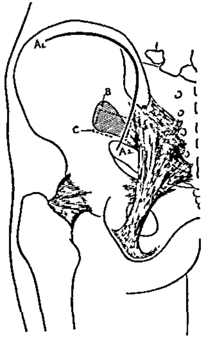

Fig. 2342.—Smith Petersen's intra-articular sacro iliac arthrodesis.

A1, A2 indicates skin incision.

B represents the area of ilium overlying the sacro-iliac joint. The rectangle C indicates the bone block which is cut out and later counter-sunk.

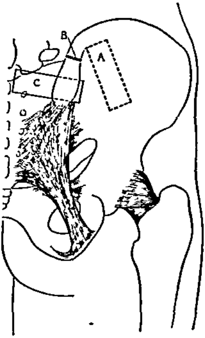

Fig. 2343.—Extra articular arthrodesis of sacro-iliac joint by use of bone graft from ilium.

A indicates graft cut.

B indicates the line of division of posterior iliac spine

C indicates the graft in position resting on rawed surface of sacrum and deep to posterior spine, which is refixed superficial to graft.

posteriorly into the inferior sacro-iliac ligament. The joint surface is then removed with a gouge or large spoon so that the window extends right into the sacrum. The rectangular piece of bone which has been removed is examined and the cartilaginous surface of it is cut away. It is then replaced and driven home, being counter-sunk as far as possible so that the cancellous tissue comes in contact with the cancellous tissue of the sacrum. If it is well home, it should fit very tightly. The muscles and periosteum are stitched back in place and the wound is closed.

Extra-articular arthrodesis may be carried out as follows: The

exposure is made as for Smith-Petersen's operation. A bone graft consisting of the outer table and cancellous tissue of the ilium, measuring 2 inches by 1 inch, is cut at some distance from the sacro-iliac joint as is indicated in figure 2343. The posterior superior spine is removed with a thin osteotome, $\frac{1}{2}$-inch of bone being elevated and turned downwards with the attached sacro-iliac ligaments. The muscles on the posterior surface of the sacrum are raised and the surface of the bone roughened; the graft is placed transversely on this raw area of the sacrum and over the area from which the posterior superior spine was removed. The posterior superior spine is then re-attached, the muscles are stitched back in place, and the wound closed.

HIP JOINT

The two easiest methods of approach to the hip joint are: (1) Antero-lateral; and (2) Lateral.

The former is used: (*a*) for drainage of the hip joint for acute arthritis; (*b*) for operations on the joint itself in children; and (*c*) sometimes for intra-articular arthrodesis.

The lateral approach is employed for: (*a*) extra-articular arthrodesis; (*b*) intra-articular arthrodesis; and (*c*) arthroplasty.

Exposure of the hip joint by the antero-lateral incision. This commences just below the crest of the ilium, 3 inches (in adults) behind the anterior superior iliac spine, and is carried forwards to below the anterior superior iliac spine and then downwards for 5 inches in the

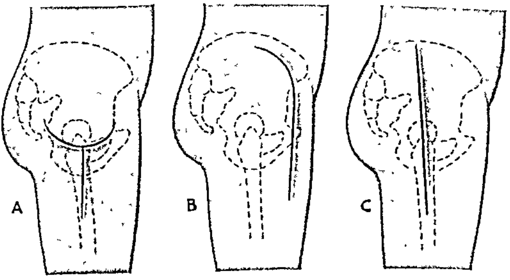

Fig. 2344.

A. Skin incision—termed the "goblet incision"—employed for most operations on the hip joint.
B. Antero-lateral or Smith Petersen incision for operations on the hip joint. This is particularly suitable for operations in children.
C. Lateral incision for hip joint, particularly suitable for extra articular arthrodesis.

line of the limb over the front of the tensor fascia femoris. The flap is turned outwards. The glutei and tensor fascia femoris are stripped from the ilium, and the interval between these muscles and the sartorius and rectus femoris is dissected. A branch of the external circumflex artery will require ligation. It will be necessary to remove the origin of the rectus femoris from the anterior inferior iliac spine in order to expose the capsule freely.

The technical part of the operation, whether it be an open reduction for a congenital dislocation, making a shelf for congenital dislocation, or drainage of the joint, will now be carried out. The muscles are fixed back in place with catgut sutures and the wound closed. If counter-incision for drainage in infective cases is necessary, this is done before the wound is closed.

Lateral incision. (i) For an extra-articular operation, a vertical incision is made in the line of the femur over the great trochanter up to the crest of the ilium: it should extend 3 inches below the great trochanter (fig. 2344c). (ii) For intra-articular operations, more room is generally necessary, and the "goblet incision" of Murphy is employed as is shown in figure 2344A. The method of exposing the hip joint is described subsequently.

Arthrodesis: Intra- or extra-articular arthrodesis may be carried out on this joint.

Indications: (*a*) Certain cases of unilateral osteo-arthritis; (*b*) Certain cases of tuberculosis; and (*c*) Flail hip joint in some cases of infantile or other paralysis.

The object of treatment of osteo-arthritis of the hip joint is the relief of pain; as a first measure of relief it is usual to advise a caliper splint to take the weight off the joint. A number of operations have been devised and it is impossible to dogmatise on the treatment of this disabling condition, particularly in elderly people. If operative treatment is contemplated, the first consideration should be whether the patient's general health, adiposity, and age will enable him to stand the operation and the after-treatment which will necessitate fixation for some weeks. Any operation is of considerable magnitude, whether it be an arthrodesis to produce bony union and so a painless joint, Jones' operation which produces a pseudarthrosis in the position of the neck of the femur, or a cheilotomy which consists in the removal of osteophytic outgrowths after division of the capsule. Arthrodesis for this condition is usually carried out by the intra-articular method, but there is no reason why the extra-articular should not be employed.

Investigation of the X-ray appearance of the hip joint after it has

been affected with tuberculosis shows that destruction of bone is common, malposition (flexion-adduction deformity) is present in many cases, and fibrous union generally occurs, so that a painful joint at the end of a tedious treatment occurs in a big proportion of cases at some time or other during the patient's life. Consequently, the tendency of surgeons of to-day is to advocate extra-articular arthrodesis, either as soon as the disease is diagnosed or at the termination of the conservative treatment. In children, free movement *may* occur in cases of early synovial tubercle and when the disease has been in the innominate bone and not in the femur. If an operation is carried out during an active tuberculous condition, a firm bony union is more likely to occur if the diseased area is not exposed.

In cases of paralysis of the lower limb, one rarely finds muscular control of the knee joint associated with excessive weakness of the muscles controlling the hip joint. When this is the case, an arthrodesis of the hip joint can be carried out. Patients with infantile paralysis accompanied by a flail limb are seldom able to walk after fixation of the hip and the knee, and these cases are often complicated by paralysis elsewhere.

Intra-articular Arthrodesis. Technique. The "goblet incision" is employed. The skin incision is somewhat undercut, and the tensor fascia femoris and glutei are separated. A broad osteotome is applied to the base of the great trochanter and this prominence removed, the bone being cut in a line with the upper border of the neck of the femur. The trochanter is drawn upwards and backwards with slight dissection so that the glutei muscles are displaced in this direction. The upper surface of the neck of the femur and capsule are then exposed, and the capsule is divided from above downwards and from before backwards. The head of the femur is then dislocated from the acetabulum, and the articular cartilage is removed from its surface. The acetabulum is then cleared of articular cartilage. These procedures are limited by many surgeons who only remove the cartilage from the superior and posterior surfaces of the head of the femur and from the corresponding surfaces of the acetabulum. One advantage of this is that the fit between head and acetabulum is somewhat better, and bony union is more likely to occur over the area where it is particularly required (see fig. 2345A).

The head is replaced in the acetabulum and fitted in; if bony surfaces do not come in contact, further trimming is necessary. Stitches through the capsule help to hold the bones in apposition. The limb is then held by the assistant in slight abduction and flexion, and the great trochanter is brought back on to the femur. It is usually found that

if this is placed on its old seating, the muscles will be lax, and that by fixing it further down the femur the head will not only be held better against the acetabulum but the abduction will be maintained; hence, a new bed is made for the trochanter lower down on the outer side of the shaft of the femur where it is fixed by two pegs or nails; the muscles are united with stitches and the wound closed. There is no doubt that a proportion of cases do not obtain bony union after this operation so that it is advantageous to employ extra-articular fixation as well.

Extra-articular Arthrodesis. Technique. This operation consists in the formation of a bridge of bone between femur and ilium to prevent movement at the hip joint. Various methods have been described as the evolution of this operation has developed, and the type of operation must depend on the condition of the patient and the nature of the lesion for which it is carried out.

Two types of operation are frequently employed:

(1) When the bridge is taken from the femur or the ilium; and

(2) When the graft is from the tibia.

If the condition is carried out for tuberculosis, tuberculous bone should not be used and the graft should not extend through the joint;

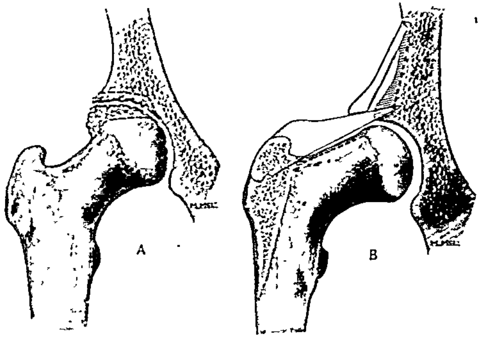

Fig. 2345.

A. Arthrodesis of the hip (partial extra articular). The bone and cartilage between the dotted lines are removed and the head of the femur is approximated to the bared roof of the acetabulum. B. Hibbs' arthrodesis of the hip joint. The anterior two-thirds of the great trochanter and a portion of the shaft are rotated after removal of the upper surface of the neck of the femur. A flap of ilium is also raised. In this diagram the graft is not shown in contact with the neck of the femur, in order that it may be clear what area of the neck of the femur is removed.

whereas, if it is carried out for non-suppurative arthritis, the strongest arthrodesis will be made by a " bridge-graft " from the ilium to the trochanter, resting directly on the neck of the femur.

Technique of Hibbs' operation. The lateral approach with the linear incision is employed by most surgeons. The muscles are separated in the interval between the gluteus medius and the gluteus maximus, and the capsule of the joint is exposed. The anterior half or more of the great trochanter and 2 to 3 inches of the adjoining femoral shaft are removed with a thin osteotome and separated in the form of a wedge. A flap of the ilium is turned up from above the acetabulum, the base of the flap being left attached. The wedge of femur is then swung round so that the pointed portion from the shaft fits into the ilium. The flap of ilium is pressed down on to the bridge and stitched over it. The stitches are also applied to keep the trochanter on the femur. As Hibbs describes this operation, the upper surface of the neck of the femur is also removed and the graft rests directly on the neck of the femur; this makes a firm arthrodesis, but should not be employed in cases of tuberculosis. Muscles are stitched back in place and the wound is closed. If there is deformity, an osteotomy must be performed later unless an intra-articular operation has been carried out at the same time.

Technique of osteoplastic flap from the ilium (after Mathieu and Wilmoth). The hip joint is exposed as for intra-articular arthrodesis of the hip by the removal of the great trochanter. A flap of bone is turned down from the ilium and fixed between the trochanter and femur. It is important that the flap from the ilium should keep good contact with that bone, as it is inclined to get away. If it is loose it should be fixed back by other portions of bone removed from the ilium (see fig. 2346).

Technique of Albee's operation. The hip joint is exposed but the trochanter is not removed. A graft is cut from the tibia and driven through a tunnel in the great trochanter so that it lies deep to the muscles along the neck of the femur and passes into a hole which is made in the ilium above the acetabulum. This operation can be modified by using a portion of free graft from the femur. This consists of the middle third of the great trochanter and upper portion of the shaft of the femur; the graft is turned round so that the portion from the shaft is driven into the ilium, and the middle portion of the trochanter is again fitted in between the two sides of it which were left standing after the graft was cut. This latter appears to be the easier operation, but the size of the bridge formed is not so large as in the operation of Hibbs though it fits well, whereas the Hibbs' graft does not

fit easily unless the upper surface of the neck of the femur is removed (fig. 2347).

It is important to realise that the relationship of the femur and the ilium must be accurately maintained while the wound is closed, dressings applied and a plaster-cast made. It is of great assistance if the plaster bed is made before the operation so that the patient can be put directly into it. Further, the operation is a severe one for the type of patient who needs it, so that the additional exposure and length of anæsthesia necessary for the application of plaster at the end of the operation are

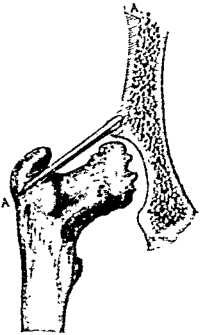

Fig. 2346.—Extra-articular arthrodesis of the hip (*after* [illegible]). Graft from the ilium is fixed between the trochanter and the neck of the femur below and into the ilium above.

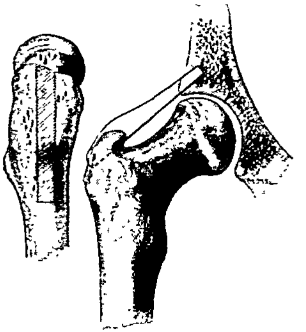

Fig. 2347.—Extra-articular arthrodesis of the hip (*after* *Albee*). A bone graft from the lateral surface of the trochanter and femur is transferred to the ilium above and to the central portion of the trochanter below.

to be avoided. It is seldom that osteotomy and extra-articular arthrodesis can be carried out at the same time. In tuberculous cases, surgeons differ in their opinion as to whether osteotomy should be done first or subsequently. In the osteo-arthritic case, this can be avoided by combining intra- and extra-articular arthrodesis. In every case the plaster must include the foot and leg of the affected side, extending to the knee on the unaffected side and upwards round the lower portion of the thorax. A deep plaster trough—of the plaster-bed type—is most suitable, and can be employed until the patient is allowed to get up. It is advisable that a short spica should be worn when the patient is getting about on crutches for the first few weeks.

Bifurcation operation. This operation, associated with the name of Lorenz, is employed both in adults and in children. In the former it is suitable for cases of osteo-arthritis of the hip joint and for un-united subcapital fractures of the neck of the femur; in children it has been employed in cases of unreduced congenital dislocation of the hip joint. The operation causes only a small degree of shock, takes a short time to carry out, and is accompanied by little hæmorrhage. As an operative procedure, the dangers are few compared with arthrodesis of the hip. More successful results will follow an "open" osteotomy than one carried out through an incision limited to the size of the osteotome.

Technique. An incision is made along the outer side of the line of the femur, 5 inches from the tip of the trochanter downwards. Dissection is carried out on the front of the femur, so as to appreciate the level of the small trochanter and the neck of the femur. With a broad osteotome, the femur is divided upwards and inwards. The bone incision starts below the great trochanter and ends above the small trochanter. The lower fragment is pushed inwards and upwards, whilst the assistant abducts the limb. The fragment should be displaced so that it rests outside the capsule, below the lower border of the acetabulum. For the success of the operation, union must occur between the two divided fragments in the altered position.

After closure of the wound, the limb is secured in plaster, which must include the lower part of the trunk and the thigh of the other limb. Abduction is not required, the limb being square to the trunk. After two months, an ambulatory plaster spica is employed (McMurray).

Arthroplasty of the hip. Indications: (1) Double ankylosis of the hips; (2) Limited painful movement in cases of arthritis, (*a*) subsequent to infection when it is certain that the infective condition is healed, and (*b*) in picked cases of osteo-arthritis of the atrophic type; (3) Rarely in cured tuberculous arthritis.

Undoubtedly this operation is called for most frequently in cases of double ankylosis. Murphy found that the hip joint gave him the best results in arthroplasty.

Technique. The hip joint is exposed by the "goblet incision" using the lateral approach, or by the antero-external incision according to the choice of the operator. The former probably gives the better exposure. After removal of the great trochanter, the hip joint is exposed. If ankylosis is firm, it is necessary to separate the femur from the pelvis by cutting away the upper and posterior surfaces of the head of the femur and then the lower portion of the head. A large gouge will then cut through the deep surface of the head, and with a little

force the remainder of the head can be fractured. If the head is not ankylosed, it is dislocated from the acetabulum. The head of the femur is then reshaped and a deep hollow made in the acetabulum. Careful cutting with a gouge will be as effective as the use of the special bits and a brace which have been devised for this purpose. It is important to smooth the acetabulum and the bony surfaces, to see that there is a big gap between the head and the acetabulum, and to remove all loose bony particles from within and around the hip joint. A piece of fascia lata, which should measure about 4 inches by $3\frac{1}{2}$ inches, is now cut from the thigh. This is placed over the head of the femur and stitched round the neck with a purse-string suture. The head is returned to the acetabulum, the trochanter replaced and the wound closed. The limb is extended on a Thomas splint. A moderate amount of abduction is used and 15-lb. traction for three weeks. The extension is then removed and the patient encouraged to contract the thigh muscles. He may get up in six weeks with crutches, and start to bear weight in eight weeks.

Whitman's reconstruction operation. This was originally devised for un-united fracture of the neck of the femur, particularly when the neck had been considerably absorbed. It is also employed for some cases of monarticular hypertrophic arthritis.

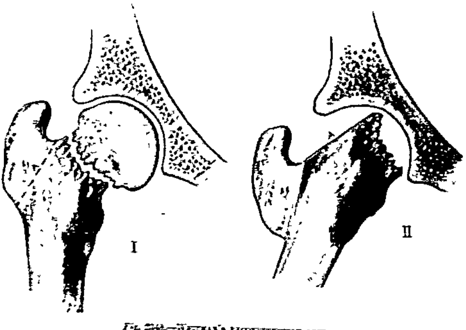

Fig. [illegible].—WHITMAN'S RECONSTRUCTION OPERATION.

I. Shows un-united fracture of neck of femur with absorption of the neck. A indicates line of section of great trochanter from the shaft.

II. The head has been removed. The neck has been placed in the acetabulum and the great trochanter placed on the outer side of the shaft of the femur.

Technique. Whitman employed a semicircular incision similar to the upper part of the goblet incision, but the incision crossed the femur 3 inches below the apex of the trochanter. The interval between the tensor fascia femoris and the gluteus medius is opened and the capsule exposed. With a broad chisel, the base of the trochanter is cut through in the line of the neck and is turned upwards with the muscles attached. The capsule is opened and the greater part of the head removed so that all cartilage, marginal exostoses, and as much of the underlying bone as may be affected in the degenerative process, are removed. In most instances, Whitman removed the whole head. The end of the neck or remains of the head is smoothed and reinserted into the acetabulum. A thin section of bone is turned back from the upper and outer surface of the shaft of the femur and the limb abducted. The trochanter is then fixed to the bare surface on the outer part of the shaft by deep sutures or a peg. The wound is closed, and a long plaster spica is applied in extension and abduction. Whitman appears to vary his after-treatment, allowing some patients to walk in a short spica and crutches after a few weeks, while others are kept recumbent until it is certain that the trochanter has united to the femur. Subsequent to this operation, it is most important that there should be persistent stretching of the limb in the direction of abduction and extension in order to prevent the limb from becoming flexed and adducted.

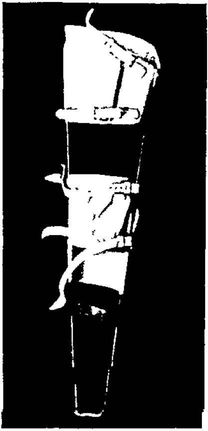

Fig 2349.—Bucket caliper.
(Beckett and Bird.)

After any operation on the hip joint, the majority of patients are more comfortable if they wear a caliper for some months after the operation.

KNEE JOINT

Arthrotomy is required for:

(1) *Suppurative Arthritis.* The operation is described in Vol. II, page 3428. It is undesirable to divide the ligamentum patellæ in order to drain the joint; such an exposure seldom produces better drainage,

and the risk of fixation of the knee in the flexed position which is employed after this incision is considerable. It is doubtful if a limb is saved by this procedure, and it is to be condemned. Drainage of the knee joint in an adult, when pus is present in the joint, is usually followed by ankylosis; it is to the patient's advantage if this ankylosis is bony with the knee fully extended or flexed only a few degrees.

(2) *Exploration of the Joint.*

(*a*) *For diagnostic purposes;*

(*b*) *For removal of loose bodies.*

A tourniquet is used, and the knee is placed on a rest or over two sand-bags so that it is flexed to about a right angle. An incision is made along the inner side of the patella and suprapatellar pouch. The capsule and synovial membrane are divided about ½-inch medial to the patella. Through this incision it is possible to examine the synovial membrane, the cartilaginous surface of the femur, and the anterior portion of the internal semilunar cartilage.

The technical portion of the operation is now carried out, such as removal of synovial membrane for examination. The wound is closed in two layers, synovial membrane being stitched with a continuous suture and the capsule with the same piece of catgut or a second suture of similar nature. A pressure-bandage is applied and no splint employed unless the condition is likely to be painful.

Loose bodies may be removed through the approach just described. If a loose body remains in one situation and is palpable through the skin, an incision should be made directly on to it, but where many loose bodies are present, an endeavour should be made to remove them through one incision. If it is possible to count how many are present in the X-ray picture, they should be recounted as they are removed. It may be advisable to make a second incision on the other side of the joint. For a loose body which cannot be found, there is probably no better method than forcible flushing with saline by means of a sterile Higginson syringe.

If a loose body is in the posterior part of the knee joint, it is necessary to remove it through a posterior incision. The patient is placed on his face with the knee extended. An incision is made just to the outer side of the mid-line and extending for the length of the popliteal space. The external popliteal nerve is exposed and drawn outwards. The *internal popliteal* nerve and vessels are drawn inwards. Care should be taken not to divide or injure the communicans fibularis and communicans tibialis nerves. The knee joint is then flexed and the space between the two retractors dissected down to the posterior liga-

ment; this is incised from above downwards, the loose bodies are removed, a stitch is placed in the capsule, the popliteal fascia is reunited, and the wound is closed.

The approach to the knee joint by *splitting the patella* is undesirable as the injury to the joint is considerable and the risk of traumatic arthritis after the operation is far greater than when the joint is opened through the soft tissues. When it is necessary to expose the joint and displace the patella laterally, this can be carried out by a long incision through the soft tissues to one side of the patella. (See also Vol. II, page 3387.)

(*c*) *Removal of the internal and external semilunar cartilages.* This has been described in Vol. II, page 3365.

(*d*) *Reconstruction of crucial ligaments.* Rupture of the crucial ligaments and fractures of the tibial spine may either be associated or exist alone. The condition is a serious one.

The *diagnosis* of ruptured crucial ligaments is made on: (i) the history of a severe injury to the knee; and (ii) finding that the tibia can be moved forwards or backwards, or rotated inwards when the leg is fully extended.

When the anterior crucial ligament is torn, it is found that the tibia will move forwards on the femur when moved passively with the leg extended, whereas in a posterior crucial ligament injury, the tibia can be displaced backwards when the knee is in the flexed position. It is doubtful if the latter injury occurs alone.

Laxity of the joint due to chronic disease (such as Charcot's disease) can be easily excluded. If, after an injury, laxity of the type described is present, but the knee cannot be extended, there is likely to be a fracture of the tibial spine.

The joint will be swollen owing to hæmorrhage and synovial fluid and will be painful, as after any serious injury to the knee.

Treatment. Fracture into the joint is excluded by a skiagram. The treatment of a fractured tibial spine is considered on page 4491.

An anæsthetic should be given, and the limb put in plaster which should include the thigh and foot. The knee should be extended at 160 degrees and the foot placed at a right angle with the leg. The patient is allowed to get about with crutches and with a patten on the opposite shoe. This plaster should remain on for three months. After that time, faradism should be employed for the quadriceps and active exercises for the knee. Stiffness is likely to be present for at least another eight weeks.

This treatment will result in a good knee in a number of patients

under the age of thirty, but in others there will be a partly flail knee, some having periodic distension of the joint with effusion.

If this treatment fails, an apparatus of the knee-cage type, with a lock to limit full extension, may be employed. Operative repair of a torn crucial ligament causing a flail knee with severe functional defect has been carried out.

The operation of *reconstruction of ruptured crucial ligaments* is difficult. Although some good results are reported, it must be considered still to be on its trial and should certainly *not* be advised unless adequate treatment on the lines suggested has been tried and failed. The principles of the operative reconstruction are: (1) Large exposure of the joint as for arthroplasty (see page 4343 and fig. 2352). The "split patella" approach should be avoided. (2) A strip of fascia, such as the ilio-tibial band, is passed through drill holes in the femur and tibia, to replace the anterior crucial ligament. (3) The fascia is pulled tight with the knee at 160 degrees and fixed extra-articularly, preferably by a bone peg knocked into the drill holes. (4) Fixation in plaster with the knee at 160 degrees for six weeks. (5) Physical treatment with knee support until the knee is strong.

Reconstruction of the posterior crucial ligament is very rarely required, but has been carried out on similar lines.

Arthrodesis. Indications: (1) Tuberculosis. In children this is seldom employed, but in adults it is the routine treatment of tubercle of the knee. (2) Fibrous ankylosis which has been painful, or when there is a tendency to flexion deformity. (3) Disorganisation of a joint, e.g. Charcot's disease. (4) Flail knee joint complicating paralysis, such as anterior poliomyelitis. Most surgeons order a caliper splint but others practise this operation.

When the operation is carried out for tuberculosis, the object is two-fold: (*a*) to remove the diseased area, and (*b*) to produce bony ankylosis.

When the operation is performed for other causes, bony ankylosis is the sole object; consequently, in cases of tuberculosis a careful dissection of synovial membrane is necessary, whereas in the other cases if bony surfaces are brought into apposition the object will be achieved.

Technique. A tourniquet is applied, and the knee is placed over sand-bags. A U-shaped incision is employed, extending from above the adductor tubercle vertically downwards crossing the front of the tibia over the insertion of the infrapatellar ligament, and upwards to above the external condyle. In a tuberculous case, any sinuses should be excised when the skin incision is made. The skin flap is dissected upwards, and the capsule and ligamentum patellæ are divided in the

same line as the skin incision and turned upwards. If the operation is being carried out for tuberculous disease, the cartilage is removed from the patella with a saw, or the patella is excised, and the synovial membrane dissected out in one piece from the suprapatellar pouch. The semilunar cartilages and crucial ligaments are removed and the synovial membrane dissected from the sides of the joint. The leg is pushed backwards so that the condyles of the femur rest on the tibia. With a saw, the lower end of the femur is removed. If there is little destruction of cartilage and bone, it may not be necessary to remove more than one-third of the condyles, but it is essential that the disease should be eradicated and that the saw-cut should be in the same plane as the original joint line. It is often necessary to excise the anterior

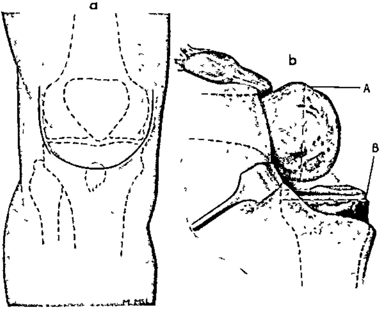

Fig. 2350.—Excision of the Knee Joint.
The skin incision is indicated in Fig a. Fig. b shows A and B, the usual lines of section of femur and tibia respectively.

portion of cartilage by a second saw-cut in the long axis of the bone. The tibia is then brought out into the wound and a thin slice removed from the upper surface. If tuberculous foci extend into the shaft, they can be gouged out or more bone can be cut away. The femur and tibia are separated and synovial membrane is dissected from the back of the joint. The leg is then extended and the divided surfaces of femur and tibia placed in apposition to test if the limb is straight. It is advisable that the thigh and leg should be straight or flexed only a few degrees. The femur and tibia are then fixed together by bone pegs $\frac{1}{8}$-inch in diameter or by thin steel pins, these being driven in through the tibia into the femur in a cross fashion. It is often easier to do this through incisions below the large one already made. It is most important that the tibia and femur should be kept

firmly together while these pins are driven home. The wound, which is made neater by trimming away superfluous capsule and skin, is then closed. The dressing is applied, the tourniquet removed, and the limb fixed in plaster-of-Paris, including the foot.

Some surgeons cut the bones so that the lower surface of the femur is rounded and the upper surface of the tibia concave. This prevents the tibia from slipping back on the femur, but the latter will not occur if pegs or pins are used. If it is considered advisable to employ a drainage-tube for forty-eight hours, it is probably wiser not to place the limb in

Fig. 2351.—Lateral and antero-posterior X-ray photographs of a knee which had been excised for osteo-arthritis three years previously.

plaster-of-Paris but on a Thomas splint. If this method of fixation is employed, the posterior half of the limb can be placed in a shell of plaster and a 4-lb. weight extension used to keep the limb still. Whatever form of fixation is employed, the limb should be raised in bed so that the weight of the leg tends to keep the tibia against the femur. Some surgeons advocate that the pelvis should be included in the plaster. After two to three weeks, the stitches are removed and a plaster-cast is applied from the top of the thigh, including the foot, preferably under an anæsthetic. It is advisable that the patient should remain recumbent for twelve weeks. The plaster is then removed, and an X-ray

photograph taken to ensure that bony union is secure before the patient is allowed to walk.

Arthroplasty of the knee. Before contemplating this operation it should be realised that a stiff knee due to bony ankylosis in a good position performs excellent function. If arthroplasty is carried out, it is essential that after the operation the joint should be painless and stable. The majority of surgeons prefer to convert fibrous ankylosis into bony ankylosis rather than risk an arthroplasty, which may do

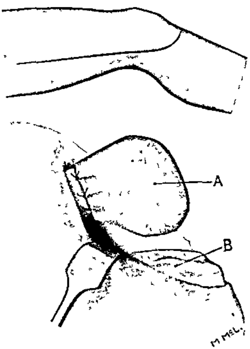

Fig 2352.—ARTHROPLASTY OF THE KNEE.
Upper fig. shows an incision which enables the joint to be exposed and a fascial flap cut from the outer side of the thigh
Lower fig. shows A, the remodelled end of the femur covered with the fascial flap and B, the upper end of the tibia.

little beyond returning the limb to the condition which obtained prior to operation (fig. 2352).

This operation has been practised for nearly forty years, but stable knees with a good range of movement were seldom reported until 1920 when Putti recorded 10 cases: the average age of these patients was 22; the largest range of movement obtained was 100 degrees, the smallest 50, and the average 82.

Technique. The incision used is a long antero-lateral one extending forwards across the front of the leg below the tibial tubercle. The tibial tubercle is detached with the infrapatellar ligament. Care should be taken to preserve ligamentous structures if this is possible. The joint is exposed and the ends of the femur and tibia shaped. The *lower end of the femur is remodelled so that it is similar to the end of a* normal femur, the groove between the condyles being well deepened.

The transverse diameter of the condyles is preserved but the antero-posterior diameter is decreased. Some surgeons aim at a V-shaped lower end of the femur, both in the antero-posterior and lateral planes. Part of the patella may have to be cut away, but it should never be completely removed. The spine of the tibia is made sharp. From the upper part of the lateral incision, fascia lata is cut, one sheet being fixed round the lower end of the femur and another piece over the top of the tibia. No patellar flap is used. If the extensor apparatus appears short, the quadriceps tendon is lengthened by the Z method. The wound is closed. and the leg and thigh are placed in a plaster gutter splint, semi-flexed with a 10-lb. extension applied to the leg. After two weeks the plaster is removed and the knee suspended to an overhead frame with a strap and pulley. In six weeks the patient walks with a caliper, but does frequent exercises. At the end of three months, function should be good.

Synovectomy. This operation is indicated in cases of chronic arthritis of non-suppurative type when there is a persistent large effusion associated with thickening of the synovial membrane. In this type of osteo-arthritis of the knee, there is generally some affection of articular cartilage and underlying bone. but the latter does not form such a prominent feature of the pathological changes as does the synovial thickening. Great improvement in the condition of many knees results from synovectomy but others return to the condition that was present prior to the operation. Experience is not yet sufficient to be dogmatic as to which cases are likely to improve.

Technique. A large incision is necessary. A long lateral incision curving forward over the tibia below the tibial tubercle is suitable, or a half ellipse with the concavity looking inwards. A half ellipse with the concavity looking outwards is undesirable, as sloughing of the flap may occur from lack of blood supply. The tibial tubercle is removed and the lateral portion of the capsule incised so as to turn up the extensor apparatus. The synovial membrane is dissected out in one sheet if possible. care being taken to remove all membrane from the supra-patellar pouch. The semilunar cartilages, the crucial ligaments and the posterior portion of the knee joint are not touched. The suprapatellar pouch is diminished in size by catgut stitches, the capsule closed laterally, and the tibial tubercle fixed back in position. The limb is placed in a gutter plaster splint for two weeks, after which time movements can be commenced. Active movement should be encouraged as soon as the patient is capable of performing it. Manipulation to break down adhesions under an anæsthetic is not desirable.

The operations for fractured patella and for other conditions of the knee joint, including lateral dislocation of the patella, are described in Vol. II, page 3390.

ANKLE JOINT

Arthrotomy is required:

(1) For removal of loose bodies from the ankle joint (such as a separated portion of articular cartilage and bone); and

(2) For suppurative arthritis.

The ankle joint can be approached from the front from either the inner or the outer side by incisions placed in front of the malleoli. Whenever possible, the outer incision is to be preferred. This extends along the anterior border of the lower quarter of the fibula lateral to the peroneus tertius. The tendon of this muscle is retracted medially, and the capsule of the joint is incised from above downwards. If sufficient exposure of the joint is not obtained, the anterior part of the capsule should be raised from the tibia. After closure of the wound it is important that the foot should be placed in plaster at a right angle to the leg.

When suppurative arthritis is proved by aspiration of the joint, the incisions are made where the distension is most obvious. If possible, drainage is provided posteriorly by an incision made on each side of the tendo Achillis. Anterior drainage is not satisfactory as the tendons are likely to fall over the incision in the capsule and thus prevent efficient drainage. The foot should be immobilised at right angles to the leg.

Arthrodesis. Indications:

(1) Traumatic arthritis, particularly associated with malunion of fractures of the ankle joint;

(2) Fibrous ankylosis which is painful;

(3) Ankylosis in faulty position.

Technique. The outer anterior incision 4 inches long is used. The tendons are drawn medially and the joint exposed. The articular cartilage is removed from the upper surface of the astragalus, from the lower surface of the tibia, and from the malleoli (see fig. 2353). It is then found that the astragalus is too loose in the mortice; it is therefore advisable to perform an osteotomy of one or both malleoli so that they can be pushed inwards and outwards to fit snugly against the astragalus. The position of the foot is then tested, as it is desirable to arrange the bones of the ankle joint so that the foot is in a few degrees of equinus. The wound is closed, and the leg and foot are placed in plaster. The plaster is changed at the end of two weeks when a tightly-fitting

F. Line of division of fibula.

cast is made, with a walking stirrup. This is retained for three months.

When the operation is carried out for ankylosis in faulty position, a wedge-shaped portion of bone is removed with the thick end of the wedge forward.

Arthrodesis of the ankle joint may be performed by driving a bone graft transversely through the fibula, the tibio-astragaloid joint line and the internal malleolus.

Arthroplasty. The functional value of an ankylosed ankle joint in good position is so great that arthrodesis is always preferable to arthroplasty. The possibility of an arthroplasty producing a stable and painless joint is so small that the operation is not advised.

JOINTS OF THE FOOT

In cases of paralysis, particularly infantile paralysis, stabilising operations on the foot are of great value when the foot is flail. They serve an equally good purpose when the foot is drawn into valgus or varus owing to paralysis of one or more groups of muscles. These operations should not be carried out on very young children owing to the interference with the growth of the foot and because further recovery of the muscles may occur. Experience has shown that, in cases of paralysis, arthrodesis of one joint only (such as the astragalo-scaphoid) does not prove satisfactory.

The best results are probably obtained by triple arthrodesis (Dunn's operation). In some cases an operation on the tarsus is of value in cases of dropped foot, and a number of surgeons employ astragalectomy (Whitman's operation) for calcaneo-valgus and other deformities of the foot.

Triple Arthrodesis of the Foot (*Dunn's operation*). This is indicated particularly in cases of flail foot and deformities due to partial paralysis of the foot. Some surgeons employ it for almost any deformity of the foot and in spastic deformities, but it is not the operation of choice in cases of pes cavus (see Vol. II, page 3356).

Technique. A tourniquet is employed, and the inner side of the foot is laid on a sand-bag.

The original skin incision employed was from in front and above the external malleolus to the dorsal surface of the base of the 5th metatarsal bone. However, most surgeons prefer to use a flap, the convex surface downwards; this extends from behind the external malleolus downwards and forwards and then across the dorsum of the foot. The flap is turned up, the extensor brevis digitorum is exposed, its origin from the os calcis is separated, and the muscle pushed forwards. The calcaneo-cuboid joint is exposed; with a thin osteotome the articular surface and a small piece of bone are removed from the front of the

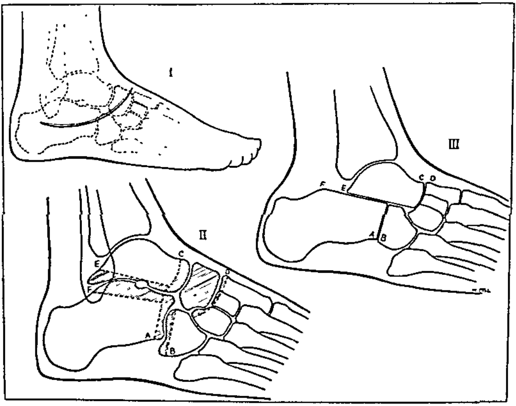

Fig. 2354.—TRIPLE ARTHRODESIS (STABILISATION) OF THE FOOT (*after Dunn*).

I shows line of skin incision.

II shows lines of bone section. A and B are cut first, C and D next, and then F and E.

III, the foot has been fitted together and displaced backwards.

The shortening of the foot depends on the amount of bone removed from the os calcis and cuboid. The amount of backward displacement of the foot depends on the amount of bone removed from the inner side of the foot.

os calcis and the back of the cuboid. The amount of bone thus removed will determine the *total shortening of the foot.*

With a periosteal elevator, the tissues are separated from the head of the astragalus and scaphoid. The anterior tibial group of tendons is retracted inwards. With a gouge, the articular cartilage and a small strip of bone are removed from the front of the astragalus. With the same gouge, the articular cartilage and a small piece of bone are removed from the proximal portion of the three cuneiform bones. This will make it possible to remove the scaphoid and the divided portion of the cuneiform bones. The removal of the scaphoid may be somewhat difficult owing to the attachment of the spring ligament and the insertion of the tibialis posticus. There should be a gap now between the bare surface of the head of the astragalus and the bases of the cuneiform bones. If these do not appear to fit, more bone should be removed until the depression in the cuneiform bones corresponds to the shape of the neck of the astragalus. The interosseous ligament is cleared from between the astragalus and os calcis so as to expose the joint surfaces. These are removed with a thin-bladed osteotome, both from the lower surface of the astragalus and from the upper surface of the os calcis. It is important that these bones should fit together, and allowance must be made for the deformity which was present before the operation.

The foot is then displaced backwards at the subastragaloid joint and is examined to see if it is square. The extensor brevis is stitched back and the wound closed. Plenty of cotton wool is employed in the dressing before the plaster-of-Paris cast is applied: this should extend from the knee and include all the foot. At the end of two weeks the plaster is removed, the stitches taken out, and a more closely-fitting plaster is applied, this is kept on for three months. If the foot is not square when the stitches are removed, an anæsthetic must be employed in order to put the foot in satisfactory position in the second plaster-cast. It should be noted that: (1) The ankle joint is not opened; (2) the shortening of the foot depends on the amount of bone removed from the os calcis and cuboid; and (3) the displacement of the foot backwards depends on the amount of bone removed from the inner side of the foot.

In valgus deformity when the peronei are active, it is usually advisable to transfer the tendons of the peronei to the inner side of the heel or of the tendo Achillis. This should not be done at the same time as the stabilisation, but can be carried out a month after that operation.

Drop foot operation (Lambrinudi). This consists in an arthrodesis of the subastragaloid joint with the formation of a natural bone block. The operation is indicated for any degree of drop foot due to paralysis

of the dorsiflexors when there is an associated varus or valgus deformity. The gastrocnemius muscle should be functioning.

Technique. A tourniquet is applied, and the foot is placed on a sandbag with the outer side facing the operator. The incision is along the posterior border of the fibula round the external malleolus extending forward to the centre of the foot over the metatarsus. The skin and soft parts are dissected forward so that the ankle is exposed, but the ligaments of the ankle joint are left intact. The astragalo-scaphoid joint is exposed and opened. A knife is carried under the neck of the astragalus, and the interosseous ligament between the astragalus and the os calcis is divided. The subastragaloid joint is freely opened and the forepart of the foot displaced inwards. The articular cartilage is removed from the upper surface of the os calcis and from the lower surface of the astragalus. A notch is cut in the postero-inferior aspect of the scaphoid.

Fig 2355.—Drop foot operation (*Lambrinudi*).

I Line A B indicates line of section of the astragalus The proposed notch in the scaphoid is indicated. II shows effect of operation The astragalus is tilted forwards so that it is locked against the scaphoid. The divided area A B now looks downwards. The head and neck have been transferred to form a block behind the astragalus.

The neck of the astragalus is then divided obliquely as is shown in figure 2355. The top of the neck of the astragalus is then fitted into the notch in the scaphoid. The foot is now placed so that it is just below a right angle to the leg; this will tilt the astragalus forward so that there is a gap between the back of the astragalus and the upper surface of the os calcis. This gap is filled in by the piece of bone, which formed the head of the astragalus, after the articular cartilage has been removed from it. The wound is closed, and plaster-casts are applied in a similar way to that employed after Dunn's operation.

Astragalo-scaphoid Arthrodesis. This operation is employed in cases of spasmodic flat foot, when there is arthritis in the joint between astragalus and scaphoid, and for arthritis if the joint is painful. Sometimes fixation is more readily achieved if the calcaneo-cuboid joint is arthrodesed at the same time.

An incision 3 inches long is made along the inner border of the foot with the centre over the joint. The tibialis anticus muscle is retracted,

the joint is defined, and the articular cartilage removed from the head of the astragalus and back of the scaphoid. The foot is adducted so that the surfaces come in contact. If there is a gap when the foot is

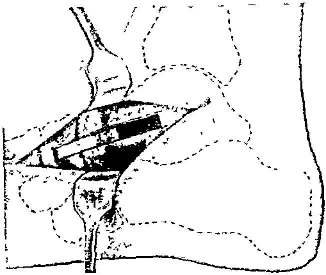

Fig. 2356.—Astragalo-scaphoid arthrodesis. The inner surface of the joint has been exposed. A graft has been cut from the inner surface of the neck of the astragalus and slid forward and inlaid into the scaphoid and astragalus.

placed in the required position, the calcaneo-cuboid joint must be fixed through a separate incision.

A small graft of bone, 1 inch long by a $\frac{1}{4}$-inch, is cut from the inner side of the neck of the astragalus and fixed to the inner side of the scaphoid and astragalus to keep them in the required position.

After closure of the wound the limb is put in plaster until a skiagram shows that bony union is firm. This may take three months.

Operations for hallux valgus are described in Vol. II, page 3348.

CHAPTER III

Tumours of Bone

A. Simple Tumours

Simple tumours are Osteoma, Chondroma, and Fibroma.

Osteoma

A *compact osteoma* grows on bones developed from membrane; it is a sessile tumour occurring on the skull, and is frequently called an *ivory exostosis* owing to its density being compared to ivory. It is usually single and most commonly grows slowly on the frontal and parietal bones. It is not attached to overlying structures but is adherent to the bone from which it arises. This growth may be found in the frontal sinus, in the walls of the external auditory meatus, or in the roof of the orbit. An osteoma occurring in one of these situations is liable to grow to remarkable dimensions, destroying the surrounding tissues and even encroaching on the cranial cavity. Pressure may be caused on the frontal lobe of the brain, and the eye may be destroyed by a tumour in the frontal sinus or orbit. This growth does not undergo malignant change, but after a number of years a portion may become separated and fall off owing to strangulation of its own blood supply.

Treatment. The removal of a compact osteoma is difficult owing to its density. Removal is only advocated when symptoms, such as deafness—as might be caused by such a growth in the external auditory meatus—necessitate operative interference. If the base of the osteoma can be located, this should be drilled in a number of places and the tumour then be removed with a mallet and chisel.

The cancellous osteoma (*exostosis*) is common and is met with at the ends of long bones. Its formation occurs before the epiphysis has joined the diaphysis; in the first place it consists of cartilage only, so that it is often called an *ossifying chondroma*. Such tumours are most commonly found at the lower end of the femur (fig. 2357), the upper end of the tibia, and the lower end of the radius. One bone only may be affected, but frequently a number of bones are found to have this tumour at their growing ends. The exostosis is usually pedunculated and remains capped with a layer of cartilage. It ceases to grow when

the epiphysis becomes fused with the diaphysis. It is usual to find that a bursa has formed between the cartilage cap and the surrounding tissues. When situated around the neck of the femur, the tumour tends to be of an irregular shape, often having a broad base, and in this situation it may grow to a considerable size (see fig. 2358).

Symptoms. Osteomata themselves are painless, and patients seek advice owing to the presence of the swelling, its increase in size, or because it gets in the way. The tumour seldom presses on nerves, but it may interfere with the movements of the joint or the smooth working

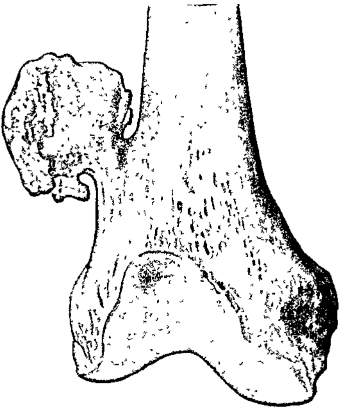

Fig. 2357.—PEDUNCULATED EXOSTOSIS OF FEMUR. IT IS HERE SHOWN COVERED WITH A CARTILAGE CAP.
(*Museum, King's College Hospital.*)

M MCLARTY

of a muscle passing over it. The bursa may increase in size and be painful if the part is knocked.

Treatment. Parents often ask for these growths to be removed from their child without their having caused any symptoms, and the removal under this circumstance is quite justifiable; likewise, removal is advocated if any of the symptoms previously described are present. If the tumour is not found until adult life and is then causing no inconvenience, there is no reason to advise its removal as malignant change does not occur.

Operation. A tourniquet is used if possible. An incision is made in

the line of the bone over the tumour, the muscles are separated and the growth exposed. Dissection is carried out until the pedicle is defined. The periosteum is divided with a knife around the base of the pedicle and pushed aside for a short distance. The pedicle is then divided with a chisel so that the contour of the bone is reduced to its normal size. The tumour and bursa are then removed, the wound closed, and the limb bandaged firmly. As a rule, this operation is simple, and

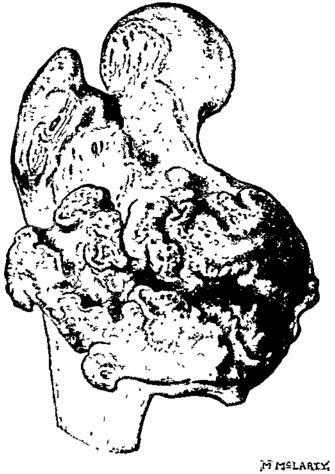

Fig 2358.—A large sessile osteoma of the upper end of the femur. The surface is rough and partly covered by cartilage. On section the tissue is cancellous bone.
(*Museum, King's College Hospital*)

difficulty only arises when the swelling is large and situated in an area which is not easy to approach. This is particularly so if there is no pedicle and if the growth occurs in a situation such as the upper end of the femur.

Subungual exostosis is a tumour growing from a distal phalanx, usually that of the big toe. Although it is possibly an osteoma, chronic irritation from the boot may be a factor in its origin. It usually grows to the size of a pea and appears between the nail and the nail-bed on the inner side of the big toe. Occasionally it is seen in the outer side

of the little toe under the nail. Ulceration may occur, and infected granulation tissue then forms around the tumour.

The treatment consists in removal of the nail and exostosis. In view of the fact that a normal nail does not always grow after this operation on the big toe, it is advocated that the terminal phalanx should be excised with the nail-bed. Such an operation is only suitable in the absence of infection around the tumour.

Multiple exostoses (*diaphysial aclasis*) is the name given to a condition affecting the ends of a number of long bones. The patient is short in stature, and the end of each bone affected is enlarged by knob-like projections. The cause of the condition is not known, but it appears that the ends of the bones are deformed owing to the modelling process, normally carried out by the sheath of periosteum, being in abeyance.

Treatment is generally not required.

CHONDROMA

Although certain characteristics are common to all chondromata, they must be considered in three categories: (1) Multiple tumours of the long bones of the hand and foot. (2) Single tumour of a long bone. (3) Single tumour of the thorax or pelvis. Rarely, a chondroma is found in the skull, usually in the region of the ethmoid bone. When occurring in the skull, symptoms of a cerebral tumour may be produced. A chondroma growing from a vertebra is occasionally seen.

Chondromata are usually encapsuled by fibrous tissue. The cartilaginous mass grows slowly and is generally lobulated. Calcification occurs especially in the fibrous septa, and the matrix between the cells may undergo mucoid or calcareous degeneration.

(1) *Multiple chondromata* of the hand and foot are probably a type of dyschondroplasia. These tumours are seen on the phalanges, metacarpal and metatarsal bones in both children and adults. In this situation there may be a single tumour or there may be a large number. The growth arises from the centre of the shaft, often near the epiphysial plate, and expands the bone. Some appear to be centrally placed, while others seem to protrude on one side of the bone, usually near the joint. The single centrally-placed tumour of a " short long bone " is probably more akin to the single tumour of the femur or tibia than a manifestation of dyschondroplasia.

The symptoms produced are due to displacement of surrounding tissues, to disability from the size of the tumour, or to the occurrence of a pathological fracture. These growths never become malignant. They do not give a well-defined shadow in the skiagr... although frequently

the line of demarcation between the tumour and bone is well defined. The destruction of the bone is seen, and such areas as are calcified show up clearly. If a portion of the chondroma ossifies, this produces a characteristic picture, and this occurs more often in a single tumour of one of the small bones of the hand or foot. Hence such a growth may be more akin to the cancellous osteoma.

The differential diagnosis is easy when the tumours are multiple.

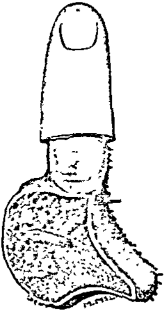

Fig 2359.—Specimen showing a chondroma of the first phalanx

(*Museum, King's College Hospital.*)

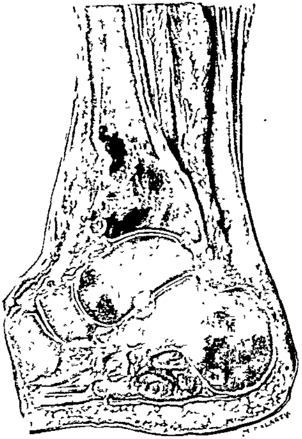

Fig 2360.—Vertical section of a leg removed for a recurrent chondroma of the tibia. A man of forty-five had a tumour excised from the lower end of the tibia. The microscopic section showed it to be a chondroma. Within two years it recurred and the leg was amputated. The section showed chondromatous tissue and blood, but there was no evidence of malignancy. He is alive nearly ten years after the amputation.

(*Museum, King's College Hospital.*)

When only one swelling is present, difficulty in the diagnosis may arise, but it should be easy to determine that the swelling is in connection with the bone; thus ganglion and tendon-sheath tumours are excluded. Inflammatory conditions of a small bone seldom affect only a portion of the shaft. The skiagram usually shows destruction of bone and

opaque areas due to calcification. Tumour substance is not visible. A giant-cell tumour is rare in these small bones, and presents somewhat similar signs and X-ray appearances. In this case expansion of the bone is usually evident, whereas in a chondroma the X-ray appearance suggests that a piece of the bone has been punched out. Fibrocystic disease of a metacarpal has similar characteristics, and a pathological fracture may occur in this condition also. The area of the cyst is less opaque than in a chondroma.

Treatment. When the tumour is single it should be removed by shelling it out from its capsule and splinting the finger. If it is not thoroughly removed it is liable to recur, particularly if it is of soft consistency. Operative treatment is equally indicated if a pathological fracture has occurred.

In cases of *multiple chondromata*, operation is only advised for the removal of a growth which is producing symptoms such as pressure on a nerve or great deformity.

(2) *The single chondroma* of a *long* bone arises in most cases near the cartilage separating the shaft from the epiphysis, but cartilaginous tumours are occasionally found in such situations as the lower third of the tibia. This type of neoplasm possibly originates from islets of cartilage which have failed to ossify in the normal ossification of the bone. It is known that these growths occur in those who have had rickets as children. They are most frequent in young adults in the lower ends of the femur and humerus. The tumour grows slowly, undergoes mucoid degeneration and frequently becomes sarcomatous.

The single chondroma is rare, and it is difficult to determine in some cases if it has arisen as a simple tumour and become malignant, or has arisen in the first place as a sarcoma and undergone cartilaginous degeneration, a condition termed chondrosarcoma.

The symptoms produced are those of pain in the region of the swelling, and the signs those of a bony tumour. The skiagram shows destruction of bone where the growth has originated ; there is no new bone formation as a rule, and the tumour does not ossify. The differential diagnosis is from other bony tumours such as giant-celled myeloma and sarcoma.

Treatment. The patient is advised that it is essential for a correct diagnosis to be made before carrying out treatment and that this can only be achieved by means of a biopsy. The pathologist's assistance is required to determine whether the tumour is simple or malignant. This task is often difficult. Those cases in which there is only cartilaginous or sarcomatous tissue are straightforward. However, experience shows that if the surgeon has any doubt as to whether the tumour is malignant

or not at the time of the biopsy, the pathologist often has a similar doubt on examining the section.

Some surgeons consider that the tumour becomes malignant if it is not already so; hence they advise radical treatment as soon as the diagnosis of a chondroma of a long bone, such as the femur, is made. This indicates that such surgeons do not recognise a simple chondroma of a large long bone, but consider cartilaginous tumours at the end of such a bone to be sarcomatous. This seems drastic in cases in which there is no sign of malignancy, but is doubtless erring on the right side when there is any doubt as to malignancy.

Local removal is advocated when cartilaginous tissue only is found. Post-operative X-ray therapy is ordered by any surgeon who considers that there is doubt about the diagnosis, either at the time of the operation or from the pathological examination. If recurrence occurs, the condition should be treated as a sarcoma. When a pathological fracture has occurred, and in certain situations, local removal may involve excision of two or more inches of a long bone, such as the femur or humerus. Fixation of the bone by a bone graft is not advocated when doubt exists as to the nature of the tumour. Briefly:

(*a*) When there is no proof of malignancy at the time of diagnosis, local removal is advocated.

(*b*) If local removal is impossible, amputation is advised at a convenient place above the growth. Treatment by X-ray therapy may be of value in this type of case, should amputation be refused.

(*c*) If malignant change is present, the case is treated as a sarcoma.

(3) *Single chondroma of pelvis or thorax.* When chondromata occur on the ribs or in the pelvis, they may grow to an enormous size. In appearance they are lobulated and pearly in colour. The larger the tumour, the larger are the lobulations. The symptoms produced are those of pressure, particularly in the pelvis. The removal of a tumour larger than a child's head has often been carried out, but the possibility of its removal depends on the position from which it arises and its relationship to large vessels and viscera. These neoplasms may grow to large proportions and remain simple, but undoubtedly malignant changes may occur.

FIBROMA

A fibroma of bone is rare except in the jaw, when it is termed fibrous epulis. A fibroma of a long bone arises from the periosteum and produces the signs of a nodular swelling fixed to the bone. It is unusual for pain to be produced, and the patient seeks treatment on account of the lump. There are no changes found on X-ray examina-

tion. The tumour should be removed and a microscopic section made to ensure that it is not an early fibrosarcoma. No recurrence will occur after removal of a simple fibroma of the periosteum.

B. MYELOMATA

In this group of tumours are to be considered:

(1) Benign giant-celled tumour, or the solitary myeloma which is often termed osteoclastoma.

(2) Multiple myelomata.

(3) Plasmacytoma: (*a*) single, (*b*) multiple.

BENIGN GIANT-CELLED TUMOUR

This is the only tumour of this group that can be said to occur with any frequency and it is probable that no more than twenty of these cases are diagnosed each year in London. The age incidence is between twenty and thirty, the neoplasm seldom occurring before twenty and rarely after forty; females are affected somewhat more commonly than males. The ends of the bone are involved, and in the epiphysial rather than in the metaphysial area. The commonest positions in which the tumour is found are the lower end of the femur and radius and the upper end of the tibia, but it may occur in all bones of the body at times—the skull, the spine and the sacrum, the clavicle, and the small bones of the hand and foot. There is almost invariably a history of injury which is followed after some months by pain and later by the formation of a swelling. There is a great tendency for the size of the tumour to increase. Pathological fracture occurs in 14 per cent of benign giant-celled tumours.

The clinical findings necessarily depend on the size of the growth. If the patient seeks treatment early, note will be taken of the history—the sequence of trauma, pain, and the formation of a swelling. The physical signs may be limited to enlargement of the end of a bone accompanied by slight tenderness. As the swelling increases, enlarged veins may be present and it may be possible to determine that the end of the bone is expanded more on one side than on the other. The swelling may feel firm but not very hard, and egg-shell crackling may be palpable owing to the thin plaques of bone present in the capsule. A very vascular tumour of some size may pulsate. At other times, the first symptom may be a fracture, or the patient will have known that a swelling was present but has not sought treatment until fracture occurred.

The X-ray appearance is that of a defect of the end of the bone;

there is expansion, usually excentric with a multicystic appearance. As a rule, there are well-formed trabeculæ. The cortex of the bone appears perforated. and thin plaques of bone may be visible on the surface of the tumour.

Examination of a specimen reveals that the central defect is essentially at the end of the bone. The tumour having started in the medulla extends outwards, and as the compact tissue at the end of the bone is thin and the periosteal defence poor, it may push aside the soft tissues. There is usually a well-defined edge across the medullary cavity down the shaft, and in the opposite direction the spread is limited by the articular cartilage. The tumour will not penetrate this and will only extend into the joint round the edge of the articular cartilage, or when a fracture has occurred into the joint, but neither of these occurrences is frequent. The trabeculæ are well defined, and the tumour tissue is reddish-brown. Often liquid blood and maroon-coloured areas are visible. Rarely, the tumour has a more cheesy appearance with small areas of hæmorrhage in it; to this rare type of tumour the name of "white myeloma" is sometimes given. The microscopic appearance is well known, the outstanding feature being a typical giant cell with its fifteen to a hundred nuclei which stain so readily.

The diagnosis is not often in doubt, probably because the radiological appearance is so characteristic. Doubt is likely to arise when the tumour appears in an atypical position such as the spine, the pelvis, a rib or a small bone. When there is doubt as to the diagnosis, a biopsy is advised. The question of biopsy of bone tumours is discussed subsequently under Sarcoma. At the time of biopsy, it may be possible to make a diagnosis from the macroscopic appearance and to proceed with treatment forthwith, or if there is any doubt, the wound is closed and a diagnosis made from the histology of the tumour substance.

Treatment. This should be by surgical measures. The methods available are:

(1) Removal of the growth, which is usually termed "scraping out" the tumour;

(2) Excision of the tumour;

(3) Amputation.

Treatment by irradiation is discussed on page 4362.

The majority of benign giant-celled tumours are treated satisfactorily by method (1). A tourniquet is employed so that the extent of the growth can be defined and removed by dissection. If fracture has not occurred, it will be possible to leave a portion of the

compact bone on the side which is least expanded. After removal of the tissue substance, many surgeons cauterise the lining with pure carbolic acid. The articular cartilage is generally exposed on its deep surface, and an endeavour should be made to avoid opening the joint.

Fig 2361 —GIANT CELLED MYELOMA OF FEMUR. SKIAGRAM TAKEN IN 1931 PRIOR TO OPERATION. THE DESTRUCTION OF BONE BY THE TUMOUR IS SHOWN AND THE LINE OF FRACTURE BOTH TRANSVERSELY AND INTO THE JOINT IS SEEN.

("*British Journal of Surgery*")

Fig 2362.—ANTERO-POSTERIOR SKIAGRAM TAKEN IN 1933 AFTER RECONSTRUCTION. THE LOWER END OF THE FEMUR WITH BOTH CONDYLES CONTAINING THE TUMOUR WAS EXCISED. THE STUMP OF FEMUR WAS IMPLANTED INTO THE TIBIA AND FIXED BY TWO OBLIQUELY PLACED BONE PEGS AND THE PATELLA. FIRM UNION OCCURRED; THE PATIENT HAD 2¾ INCHES OF SHORTENING IN THE LIMB AND COULD WALK AS MUCH AS SHE WISHED.

("*British Journal of Surgery.*")

The cavity left can be filled with bone grafts taken from another bone. It is better to use a few grafts the size of a lead pencil rather than to fill up the cavity with bone chips. Splinting is required after the operation.

When a pathological fracture has occurred or when the swelling is large so that the whole of the end of the bone is expanded, it may seem unlikely that it will be possible to remove the tumour, provide stability

for the bone and leave a satisfactory joint. Although it is wise to take the optimistic view of the effect of the first suggested method of treatment, this may be impossible, particularly at the lower end of the femur. Resection of a portion of the bone with some reconstruction operation, generally ankylosing the joint, may be of value and save amputation.

When there has been gross destruction of over 3 inches of the lower end of the femur or of the upper end of the tibia, amputation may be required. Reconstruction is more likely to be possible in the radius or humerus.

The operator should take infinite pains to remove all the tumour substance, as it seems probable that cases of recurrence only occur after operation if there has been imperfect removal.

The insertion of any form of radium into these tumours is not advised. It appears that it has either no effect or else tends to increase the growth of the tumour.

X-ray therapy has been employed in recent years both alone and in association with surgical treatment. A number of surgeons state that the giant-celled tumour is not sensitive to deep X-ray therapy. However, there is no doubt that if a surgical measure such as partial removal of the tumour has been employed, after-treatment by deep X-ray therapy produces a satisfactory result. I have operated on a giant-celled tumour of the sacrum, on one in the innominate bone of a boy aged nine, and also on a large growth of the vertebral end of a rib involving the bodies of two vertebræ. In none of these three cases was it possible to remove all the tumour substance, and post-operative deep X-ray therapy was employed. The serial skiagrams showed the sclerosis of new-formed bone as the tumour substance disappeared; there has been no recurrence of the growth of these three tumours.

The prognosis is good if surgical removal is complete and if, when incomplete, X-ray therapy is employed. The formation of metastases does not occur.

MULTIPLE MYELOMATA

These occur between the ages of forty and seventy; they are rare and very malignant. Each tumour arises from marrow and there are multiple lesions. Most commonly the flat bones are affected first—the sternum, ribs, vertebræ, skull and pelvis. Pain is a prominent feature. Bence-Jones bodies are present in 65 per cent of cases and the remainder of the cases have otherwise similar clinical features. The patients usually seek treatment because of a pathological fracture, which occurs in 60 per cent of the cases. A large swelling on the sternum or skull may

be the cause of the patient seeking advice. The X-ray appearance is a clear punched-out area in the bone. Examination of the growth shows bone destruction, and the tumour tissue, which bleeds readily, is surrounded by a bony shell. The marrow is replaced by greyish or reddish material. The microscopic appearance resembles that of a Ewing's tumour which is discussed under Sarcoma, but the cytology is less uniform. Plasma cells and lymphocytes are present in large numbers.

It is characteristic of this condition that spread occurs to other bones but seldom to the liver, spleen or lungs. The patients usually suffer from bronchitis and emphysema, and the blood count shows a secondary anæmia. It is typical for the kidneys to show nephritis with degeneration of the tubules and the presence of calcium in the convoluted tubules. The treatment of the condition is unsatisfactory; X-ray therapy is usually employed, and this irradiation produces a characteristic effect in that the tumours melt away, but soon reappear.

PLASMACYTOMA

This is a rare growth found in the shaft of long bones, particularly in the humerus and the femur. As a rule, there are no symptoms of the condition until a pathological fracture occurs through the tumour. The skiagram will show destruction of the bone, generally for two inches, with expansion and a clear area. The tumour substance has the appearance of blood clot. The microscopic appearance suggests a mass of plasma cells. Blood-corpuscles are present in certain areas. Lymphocytes may be seen but not to the extent that they are seen in myelomata.

When the condition is suspected, other skiagrams are taken to exclude multiple myelomata, and the urine is examined to ensure the absence of Bence-Jones bodies. A biopsy will show the microscopic appearance. The treatment consists in the removal of all the tumour tissue and the approximation of the ends of the bones with an intramedullary bone graft. Unfortunately, the bone around the tumour seldom has much reaction and, although the tumour may not recur, the bone graft may absorb and leave an un-united bone. There is no tendency to the formation of metastases in the solitary plasmacytoma.

Multiple tumours of the plasmacytoma type are probably an entity and a form of multiple myelomata. The urine is normal. The diagnosis must rest on the histological examination of a tumour.

C. PRIMARY MALIGNANT TUMOURS

SARCOMATA

(1) Osteogenic sarcoma.
(2) Ewing's sarcoma.
(3) Extra-periosteal fibrosarcoma.

OSTEOGENIC SARCOMA

This name is applied to the common primary malignant bone tumour. Text-book classifications are derived from the presumed area of origin or from the predominance of one type of tissue in the growth.

Osteogenic sarcoma is most common between the ages of ten and thirty, and is rare after the age of fifty, so that it is essentially an affection of youth. The tumour is found most frequently at the lower end of the femur and at the upper end of the tibia: the upper end of the humerus, the ilium, the upper end of the femur and the shaft of the tibia are less common sites. The metaphysis is the site in the long bone which is most commonly attacked.

There is a definite history of trauma in many cases: a few of these neoplasms arise in a bone affected with osteitis deformans (Paget's disease of bone).

majority of cases whatever treatment is carried out. Metastases in the lungs are generally first shown by pleural effusion. The spread is by the blood stream, but it is unusual in this type of tumour to find metastases in other bones.

Diagnosis. The problem of diagnosis is more difficult in the early stages, and at this time is very important. The history of pain and the

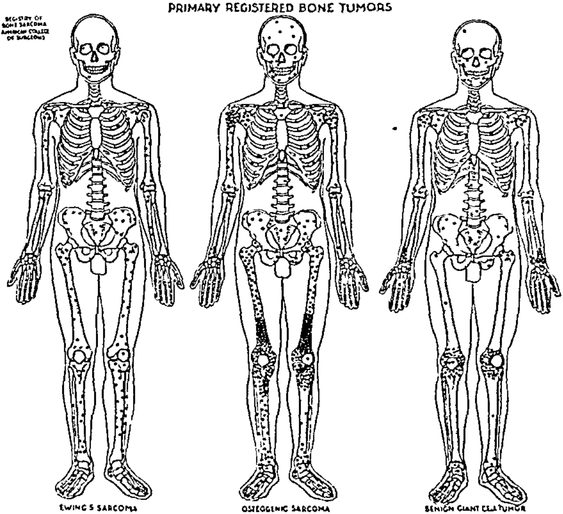

Fig. 2363.—Diagram to illustrate sites of tumours recorded by Registry of Bone Sarcoma. (*American College of Surgeons.*)

onset of a tumour with the signs already described will bring under consideration a number of lesions. No one will neglect to have an X-ray photograph. Unfortunately, in the early stages the X-ray picture is seldom characteristic. Often it is noticeable that there is some change in the bone with a less definite outline of compact tissue and medulla, both of which appear fluffy. One often feels that the skiagram is bad, but this is constantly seen in the early stages of sarcoma. At this time there may be a thin layer of new bone formation

C. PRIMARY MALIGNANT TUMOURS

SARCOMATA

(1) Osteogenic sarcoma.
(2) Ewing's sarcoma.
(3) Extra-periosteal fibrosarcoma.

OSTEOGENIC SARCOMA

This name is applied to the common primary malignant bone tumour. Text-book classifications are derived from the presumed area of origin or from the predominance of one type of tissue in the growth.

Osteogenic sarcoma is most common between the ages of ten and thirty, and is rare after the age of fifty, so that it is essentially an affection of youth. The tumour is found most frequently at the lower end of the femur and at the upper end of the tibia: the upper end of the humerus, the ilium, the upper end of the femur and the shaft of the tibia are less common sites. The metaphysis is the site in the long bone which is most commonly attacked.

There is a definite history of trauma in many cases; a few of these neoplasms arise in a bone affected with osteitis deformans (Paget's disease of bone).

Pain is usually the first symptom. A few patients seek treatment because a swelling is present. Sometimes, in the case of sarcoma of the femur or tibia, the patient has noticed a swollen knee joint.

The tumour in the early stages is felt as a swelling on one side of the bone; it is usually tender and there may be enlargement of the subcutaneous veins. Some of these sarcomata feel hard, but when destruction is a prominent feature (osteolytic sarcoma) the swelling feels soft and often spongy. If the latter contains a lot of blood it may pulsate, but the other forms of sarcoma do not show this sign. Effusion into the neighbouring joint is common when the tumour is near the articular cartilage, but there is no thickening of the joint. When the growth is large, its edges are well defined, and owing to the stretching or destruction of muscles, function becomes impaired. The patient's general health is affected sooner or later, generally before secondary deposits are present. This is shown by anæmia, loss of flesh, and pallor, particularly of the face.

Pathological fracture is uncommon, occurring in probably fewer than 10 per cent of cases. It is most likely to be seen in the lower quarter of the femur and below the neck of the humerus.

Dissemination is inevitable without treatment, and occurs in the

majority of cases whatever treatment is carried out. Metastases in the lungs are generally first shown by pleural effusion. The spread is by the blood stream, but it is unusual in this type of tumour to find metastases in other bones.

Diagnosis. The problem of diagnosis is more difficult in the early stages, and at this time is very important. The history of pain and the

PRIMARY REGISTERED BONE TUMORS

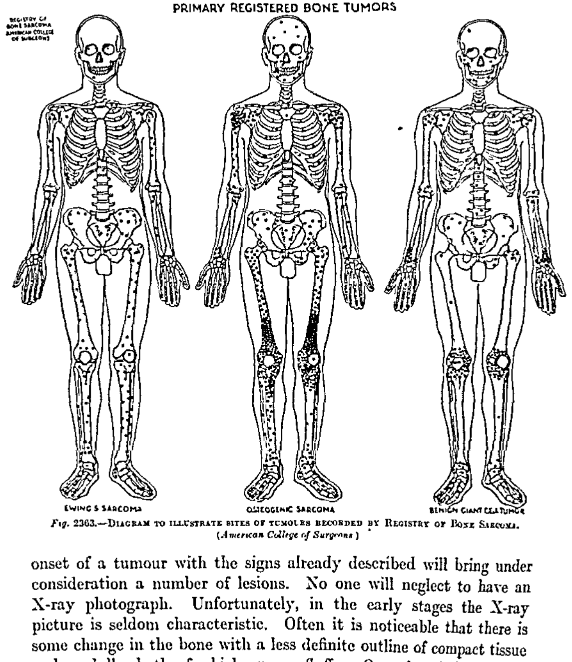

Fig. 2363.—DIAGRAM TO ILLUSTRATE SITES OF TUMOURS RECORDED BY REGISTRY OF BONE SARCOMA. (*American College of Surgeons.*)

onset of a tumour with the signs already described will bring under consideration a number of lesions. No one will neglect to have an X-ray photograph. Unfortunately, in the early stages the X-ray picture is seldom characteristic. Often it is noticeable that there is some change in the bone with a less definite outline of compact tissue and medulla, both of which appear fluffy. One often feels that the skiagram is bad, but this is constantly seen in the early stages of sarcoma. At this time there may be a thin layer of new bone formation

on the surface of the bone, the new bone being parallel to the shaft. A Wassermann reaction should be carried out, and if strongly positive it is obviously in favour of the bony change being a gumma. Syphilitic osteitis, i.e. a diffuse gummatous condition, is not likely to cause difficulty in diagnosis. A subperiosteal hæmatoma which has ossified or traumatic myositis ossificans may have to be considered. More frequently. low-grade osteomyelitis causes difficulty in diagnosis from an early sarcoma. In this connection, a leucocyte count may be of assistance.

At a later stage. a spindle-shaped swelling is often present or a large swelling on one side of the bone, and a differential diagnosis is one of interest rather than of great difficulty. Giant-celled tumour, cyst,

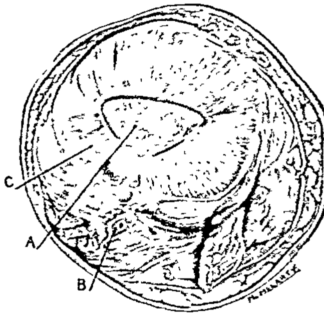

Fig. 2364.—A TRANSVERSE SECTION OF THE LEG SHOWING AN OSTEOGENIC SARCOMA.

A. Tibia. B. Fibula. C. The caseous striæ at right angles to the shaft of the tibia.

The history is interesting. A boy of nineteen years had a tumour which was thought to be non-malignant and was excised in 1919. A bone graft was inserted. The tibia united, and five years later he sought treatment for the swelling caused by the growth. He died two years after an amputation.

(*Museum, King's College Hospital.*)

and gumma are generally under consideration. The X-ray appearance at this time is more characteristic. The outline of the swelling is usually visible as a " soft tissue " swelling. There is a small lip of new bone formation under the periosteum at the edges of the tumour, and there is destruction of compact tissue and erosion of medulla. Osteogenic sarcoma will show spicules of bone at right angles to the long axis of the bone; these are lines of ossification which are present in fewer than 20 per cent of cases altogether. and seldom occur in small tumours.

The certain diagnostic method is *biopsy*—the removal and pathological examination of a portion of the tumour. This is carried out by the majority of surgeons in this country as a means of conclusive diagnosis in order that the utmost may be done in the treatment of the condition. The advantage of this method of diagnosis is not purely to

satisfy the surgeon's mind that the patient has a tumour (which even at that time may be inoperable) but to ensure that he is not dealing with a less malignant condition. When possible, a tourniquet should be used and a specimen of reasonable size should be removed, avoiding blood-vessels. The capsule of the tumour, for such usually exists, should be closed after the portion for examination has been removed. The wound should then be closed. The value of frozen section is probably negligible and it is advised that the surgeon should carry out no operative procedure beyond the biopsy at this time. The pathologist should be given the portion of tumour and afforded every opportunity to carry out his investigations with efficient fixation and staining. Those who are against biopsy state that dissemination occurs owing to incision into the tumour ; there does not appear to be any proof of this occurrence if it is carried out with due care. Further, it is stated that valuable information is not always obtained from the microscopic section ; this is most likely to be the case when frozen sections are examined or the piece of material presented to the pathologist is either minute or consists of œdematous material from around the tumour instead of a portion of tumour substance. Biopsy should be an essential part of the diagnosis. At times undoubtedly the surgeon will at the operation of biopsy find an inflammatory and not a neoplastic condition which he will recognise from the macroscopic appearance ; this will obviously be to the satisfaction of the patient as well as of himself.

Pathology. This tumour spreads slowly through the compact tissue whilst it spreads up and down the medulla. The periosteum appears to be stretched, and some time elapses before the tumour substance penetrates it and starts to invade the soft parts. Eventually the skin may be thinned and ulcerated, the mass fungating and discharging. It is characteristic of the osteogenic sarcoma that some new bone is formed, and that the growth is of varying consistency (the osteolytic soft and the sclerosing firm), whereas the innocent giant-celled tumour destroys bone.

The characteristic histological picture displays the presence of spindle cells. These are small or large and there are often polyhedral cells. The giant cells which are present are not numerous, and are smaller and have fewer nuclei than those of the giant-celled tumour. The intercellular matrix varies in different types of tissue to such an extent that these tumours have been known as chondro-, fibro-, osteo- and myxo-sarcomata. When there is gross bone destruction, the condition is well named osteolytic. The treatment of osteogenic sarcoma is considered after the description of Ewing's tumour.

EWING'S TUMOUR

This tumour represents 15 per cent of all sarcomata. It is essentially a condition of the young adult. It has been recorded at the age of four and a half, but the majority of cases occur between ten and twenty-five and seldom over forty years of age. Males suffer twice as frequently as females. A history of trauma is present in one-third of the cases.

It is a tumour of the mid-shaft area of bone, the epiphysis never being attacked primarily. The bones affected in order of frequency are the tibia, femur, humerus, fibula and ilium. Growth occurs rapidly.

The first symptom is pain, and the severity of this varies. In the early stage it is often intermittent, but later persistent and severe. Intermittent pyrexia is present in many cases and pain is usually severe during the period of fever. A leucocytosis of over 10,000 is often found. The tumour is on the shaft of the bone, feels firm and elastic, and is tender, particularly during an attack of fever. The interesting feature is that periodic decrease in size may occur. Pathological fracture is very rare.

The X-ray appearance in the early stage shows the cortex of the bone to be thickened, chiefly owing to the new bone formation parallel with the shaft of the bone. Sun-ray spicules may be present as the tumour grows. Later, a patchy destruction of bone is usually seen.

The morbid anatomy is well known. The shaft of the bone is expanded by diffuse infiltration. This leads to widening and increased density of the compact tissue and to mottling of the marrow. New bone formation occurs early and is usually parallel to the long axis of the bone, but sometimes presents an ill-defined sun-ray appearance. This formation of new bone often appears to precede destruction of the normal bony elements and is secondary to infiltration of the bone by the tumour. It arises in the subperiosteal plane, or intra-cortically. Possibly this has a relationship to lymph channels. Its presence certainly accounts for the rarity of pathological fracture. The tumour material consists of a soft necrotic mass, not unlike brain tissue in appearance. The medullary cavity is diminished, not so much by growth as by new bone formation.

Histologically, the tumour consists of small round and polyhedral cells with round or oval nuclei. They are packed closely together and often in clumps. Osteoclast giant cells are found around areas of necrotic bone. The cytoplasm is scanty and nearly stainless. In some tumours fibrous trabeculæ are seen. There is a variation in vascularity, the

blood being in spaces between tumour substance with embryonic vessel walls only.

The metastases occur in the lungs, lymph nodes and bones, particularly the skull, spine, scapula and clavicle. Secondary deposits may occur two and a half months after the onset of symptoms and usually within one year. Sometimes patients do not seek advice until

Fig 2365.—SARCOMA OF FEMUR—PROBABLY TO BE CLASSIFIED AS A FIBROSARCOMA, WHICH FOLLOWED MULTILOCULAR FIBROCYSTIC DISEASE OF THE SAME AREA. THE PATIENT WAS FORTY WHEN HE HAD A SPONTANEOUS FRACTURE THROUGH THE CYSTIC AREA. THIS OCCURRED A SECOND TIME ONE YEAR LATER. AFTER ANOTHER YEAR HE NOTICED A MASS ON THE OUTER SIDE OF THE THIGH. THE LIMB WAS DISARTICULATED AT THE HIP JOINT. HE WAS ALIVE AND WELL SIX YEARS LATER.

(*Museum, King's College Hospital*)

swellings are present in more than one bone. It is not known in what tissue this tumour originates. Some consider it to be a primary growth of bone-marrow cells and not a tumour of a true bony tissue—hence the name *endothelial myeloma* by which it is also known.

Diagnosis. Skiagrams and Wassermann reaction should be aids to the diagnosis. Confusion in the early stages is likely to arise between types of osteomyelitis and Ewing's tumour. In the later stages the

clinical picture and X-ray appearance should cause little difficulty, as neither resembles other simple or malignant tumours at all closely.

Enlargement of the shaft of a long bone occurs in osteomyelitis of low-grade virulence and in syphilitic osteitis. Differential diagnosis from the former is made more difficult by Ewing's tumour causing periodic pyrexia and leucocytosis. The pain of chronic osteomyelitis is less severe and, although it may be intermittent, does not tend to increase weekly. The X-ray appearance should aid the diagnosis, for the new bone and areas of rarefaction are more irregular in the inflammatory condition, and sequestra may be present. In the rare sclerosing osteitis which Garré described, the tibia is frequently affected and the history is one of long standing. The severe pain which the patient may have had at the onset seldom continues, and a chronic "bone ache" persists.

Irradiation may be employed as a means to diagnosis. This is referred to under Treatment. If more than one tumour in bone is present when the patient first seeks advice, the diagnosis from multiple myelomata may cause difficulty.

PERIOSTEAL FIBROSARCOMA

This is a tumour of periosteum, which may become large but does not cause destruction of bone. Pain is present. but is not of the same intensity as in bone-destroying growths.

The swelling is hard, attached to the bone. well defined, and usually surrounds the shaft. The soft tissue shadow of the tumour is visible in the skiagram. and as the neoplasm grows there may be a reaction over the bone shown by a thin layer of subperiosteal new bone parallel to the shaft.

TREATMENT AND PROGNOSIS OF SARCOMATA OF BONE

A biopsy is advised prior to the treatment. for the reasons already stated. The chest is examined by X-rays for evidence of metastasis. The methods of treatment available are:

(1) Local removal of the tumour with or without resection of a length of shaft of the bone.

(2) Amputation.

Either of these can be combined with:

(3) Irradiation by high voltage X-ray therapy, or

(4) Injection of Coley's fluid. sometimes called toxin treatment. The irradiation and toxin treatment can be combined.

(5) Radium treatment.

The treatment advised for *osteogenic sarcoma* is amputation. When possible this should be planned so as to remove the whole length of the affected bone and the whole length of muscles covering the tumour. Thus, a mid-thigh amputation is employed for a tumour of the tibia, and a disarticulation at the hip joint for a femoral growth. The lungs should be treated by irradiation at regular intervals. In America and a few British clinics, Coley's fluid is employed after amputation. Local removal combined with other treatment is not advised, and partial removal is likely to cause rapid spread. Treatment of the growth with radium generally makes it grow more rapidly, and irradiation is of no benefit, especially in the sclerosing type of growth. When cartilage forms a large part of the osteogenic sarcoma, irradiation is sometimes effective in treatment. When operation is contra-indicated owing to local or metastatic conditions, Coley's fluid is advised. The younger the patient, the worse is the prognosis. In the report of the American Bone Sarcoma Registry published in 1935, there were 74 patients with osteogenic sarcoma alive after 5 years. Of these 39 were treated by operation alone and 35 by operation combined with irradiation or Coley's fluid or both.

In the treatment of *Ewing's tumour*, it has been found that irradiation diminishes the size of the growth. It does not effect a permanent cure. Probably it is of advantage to irradiate the tumour prior to surgical intervention, and this is advised. Amputation is considered to provide a better chance of survival than local resection. Surgery with irradiation probably produces 10 per cent of survivors for over five years, but the average post-operative life after all forms of treatment is only sixteen months. Many cases do not seek treatment until symptoms have been present for a year. The American Bone Sarcoma Registry reported 10 survivors after 5 years out of 126 cases, all of whom were treated by surgical measures (7 amputations, 3 excisions of the tumour). Of the 7 amputations, 5 received both toxin treatment and irradiation.

The periosteal fibrosarcoma should be treated by surgical measures —excision in the early stages and amputation later. The tumour is of low-grade malignancy.

Treatment by Coley's fluid has been less successful in this country than in his own hands. His own statistics are of interest:

Of 126 *sarcomata of long bones* 56 survived 5 years—osteogenic sarcoma 35, Ewing's tumour 21 :

$$\left.\begin{array}{l}\text{Amputation was employed in } 35\\ \text{Local resection } \quad ,, \quad\quad ,, \quad 21\end{array}\right\}\text{ Of these 47 received toxin treatment.}$$

CHARACTERISTICS OF CERTAIN BONE TUMOURS

Type.	Age (years)	Sex.	Site.	Bones.*	History.	Path. Fracture.	Metastases.	Radiographic appearance.

* Commonest bones affected in order of frequency.

time is thus much increased. If two distinct sets of X-ray apparatus are available, some time can be saved in the taking of the antero-posterior and lateral views.

Technique. The patient is anæsthetised and placed upon an orthopædic table fitted with perineal post and traction apparatus for the feet. Traction is applied with the feet about 12 inches apart and the legs rolled slightly inwards.

The direction of the neck of the femur is estimated in the following manner:

A point 1 cm. below the middle of Poupart's ligament is marked on the skin by a small piece of lead. This marks the highest point of the head of the femur. Another point is marked by lead about 8 cms. below the tip of the trochanter. The line joining these two marks indicates the direction of the femoral neck. Antero-posterior and lateral skiagrams are now taken and the accuracy of reduction and position of the neck, relative to the lead marks, is checked. If correct, a small incision is made at the base of the trochanter and a Kirschner wire drilled into the neck, using the lead marks as a guide. It is best to insert three wires in all, the second and third being above and below the first, but in the same horizontal plane. The length of wire to be inserted must be carefully checked beforehand, by measurement from the normal femur in the manner described under the "open" method.

Another set of X-ray pictures is taken, and the position of the wires observed, in both the antero-posterior and the lateral views. A correctly-placed wire should be exactly in the centre of the neck and head, both in the vertical and in the horizontal planes. (Should none be in a sufficiently good position, the wires must be extracted and re-inserted.)

The wire in the best position is left *in situ* and the others are withdrawn.

A Smith-Petersen nail, of the requisite length, is now threaded over the guide and hammered home with the hollow punch, care being taken not to drive the guide in with it. The guide is withdrawn, traction is released, and the neck is gently impacted into the head with the impactor. The function of impaction is to close the gap between the fragments, and it should not be too vigorously employed. The nail is driven home once more and the small incision sutured.

Finally, a third set of X-ray films is taken to check the position of the fracture and nail. Should either prove to be unsatisfactory, the nail must be withdrawn with the extractor and the whole operation repeated. (Withdrawal of the fully inserted nail is often extremely

For these cases, two methods are applicable:

(1) *Plaster-of-Paris Spica.*

Suitable cases:

(a) *Sub-capital Fractures*:

(i) Some cases of adduction fractures unsuitable for operation.

(ii) Abduction fractures.

(b) *Basal Fractures.*

(c) *Per-trochanteric fractures with no displacement.*

"*Whitman's Abduction Treatment" for (a) and (b).*

Until the Smith-Petersen operation became fashionable this was the standard method of dealing with fractures in the region of the hip joint. It is claimed that bony union is obtained in about 66 per cent of cases of all ages.

The method, though usually considered in relation to cervical fractures, is also applicable to basal fractures.

The *principles* are simple: (i) Reduction of deformity by manual traction. (ii) Locking of the fragments by full abduction and internal rotation of the leg. (This is brought about partly by the tension of the anterior part of the capsule, and partly by leverage of the femoral neck against the upper lip of the acetabulum.) (iii) Fixation of the leg in the position of abduction and internal rotation by means of a plaster spica.

Details. The patient is anæsthetised on an orthopædic table. Stockinette is applied smoothly to cover the whole of the injured leg and the body as high as the axillæ, the skin being previously powdered. Each leg is held by an assistant and equal traction is applied, the patellæ being rolled inwards. The surgeon applies pressure over the region of the trochanter. Both legs are then abducted as fully as possible, *care being taken that the pelvis is maintained square with the body.*

Accuracy of reduction may be checked by measurements, or by X ray examination.

Sheet wadding is applied, paying special attention to the padding of bony prominences, such as the sacrum, trochanter, spinous processes, anterior spines, and malleoli. It is better to use felt over these prominences if the patient is thin. Plaster bandages are used to construct a spica, which must extend from the axilla on the non-affected side, including the pelvis and the whole of the affected limb. The knee is flexed to about 30 degrees.

A well-applied spica should fulfil the following conditions:

(i) Affected limb :	Full abduction.
	Full extension.
	Slight internal rotation, maintained by flexion of the knee.
	Foot at right angles.
(ii) Sound limb :	Free. Full flexion should be permitted.

After-Treatment.

(i) Skiagrams to check position of fragments.

(ii) Prevention of sores by nursing patient part-time on back, then on face, and then on sides.

(iii) Raising *head* of bed to avoid congestion.

Duration. A period of *three* months in the spica will be required for a cervical fracture, and rather less for a basal fracture. Following this, a month in bed, during which time massage and exercises are given, and finally a period of ambulatory treatment for a further two or three months, during which time a weight-bearing caliper is worn.

Difficulties of abduction methods. The construction of a plaster spica which will stand up to the strain and stress of three months' nursing is *no mean undertaking.* Some 20–30 bandages (6–8 inches wide) are necessary. Sores are apt to develop, in spite of every care. The nursing of such a case is heavy, and lifting will require at least four helpers.

When plaster is employed for a *sub-capital abduction fracture,* a short plaster spica with the leg in " adduction " is made, walking being allowed from an early date.

(2) *Simple Traction.*

The methods of treatment already described are unsuitable for the *aged or infirm.* Nevertheless, a definite line of treatment should be instituted, although the hope of obtaining a firm union by bone is remote, and the best that can be hoped for is a fibrous ankylosis.

The practice of putting the patient to bed with the legs " between sand-bags " is to be condemned. Fixation of the leg in this way merely ensures that whenever the body is moved, movement inevitably takes place at the fracture line, causing considerable pain and discomfort. These patients should be " put up " on a simple weight extension applied either by adhesive strapping, or, better, by a Kirschner wire inserted through the crest of the tibia. Rotation can be controlled in this way. Counter-extension is made by raising the foot of the bed.

The leg is allowed to lie on a Thomas splint, bent at the knee, or on a Braun frame. The foot must be kept at right angles. A weight of 10–15 lb. will be sufficient. The weight extension is continued for about

three weeks, but a skiagram should be taken after a few days, to check the correctness of the weight. Should this be too small, coxa vara will persist, or if too large, coxa valga may result. The patient is then provided with a walking caliper and allowed to get about, at first with crutches, and later with the aid of sticks. The caliper will probably need to be worn permanently.

Basal Fracture

This type of fracture is usually impacted, and therefore little displacement is the rule. Bony union is to be expected.

Two methods of treatment may be adopted: (1) Fixation in a plaster-cast, on the lines of the Whitman method already described; or (2) Treatment on a Thomas or Braun splint by moderate traction, even if the fracture is impacted. Recumbency for about twelve weeks will be required and a walking caliper is advisable for six months afterwards.

Per-trochanteric Fracture

This type is often accompanied by shortening and coxa vara. The lesser trochanter may be separated from the shaft. The mechanism, according to statistics of 207 cases (Stebbing), is that the body weight is suddenly thrown on to the femur when the leg is in *adduction.* Direct blows on the trochanter are rarely causative. This view is contrary to the usual teaching and is not supported by experiments upon the cadaver.

The *treatment* consists of continuous weight extension for a period of 12–14 weeks. Maintenance of internal rotation and abduction are of importance and a walking caliper should be used subsequently.

(Details of weight extension and the prevention of stiffness of the knee are considered under Fractures of the Shaft of the Femur. See page 4481.)

Treatment of Non-union in Fractures of the Femoral Head

Given a case of un-united fracture of the neck of the femur, the question arises, Should anything be done, and if so, what?

The answer to the first part of the question can only be found by study of the individual case. Age, condition, amount of disability, and presence of pain must all be considered. X-ray pictures must be taken to determine the degree of deformity and the condition of the femoral head. If the bone density of the head is similar to that of the shaft, it may be assumed that the head is still living. If the head is dense, it is probably avascular and dead. In the presence of an avascular

or an absorbed " head," operative fixation of the fracture by nailing is obviously useless, and consideration may be given to some form of reconstructive procedure.

Successful reduction and fixation of an un-united fracture has been seen by the author in a middle-aged man, a year after the original injury.

The following *methods of treatment* are available:

(1) *Fixation of the Fracture* (femoral head alive).

(*a*) Skeletal traction in an endeavour to overcome coxa vara.

If successful, (*b*) Fixation of fracture by Smith-Petersen nail.

(i) Open operation in order to freshen bone-ends.

(ii) By " blind " method.

(*c*) Fixation by bone graft.

(2) *Osteotomy* (Sub-trochanteric).

(*a*) *Simple*—in order to restore the normal relationship between the shaft and neck of the bone.

(*b*) *Bifurcation operation.* An oblique osteotomy is made through a 5-inch incision over and below the great trochanter. The shaft is displaced inwards so that it lies partly under the head and partly under the lower border of the acetabulum. This is controlled by direct vision. Fixation is effected by a plaster spica for 3–4 months. Bony union should occur between the shaft, head and trochanteric region.

The latter is the method of choice, as in a simple osteotomy the fibrous union at the site of fracture persists.

(3) *Reconstruction operation* (e.g. Whitman's).

(4) *Arthrodesis of the hip joint.* (This is difficult and liable to failure.)

Separation of the Upper Epiphysis of the Femur

Fractures in the region of the femoral neck are uncommon in children and adolescents, but when they occur the epiphysial line is often involved. Treatment should be on conservative lines either by continuous traction or by reduction and fixation in a plaster spica.

Of different ætiology is the " so-called " " slipped epiphysis " of the upper end of the femur.

The condition occurs in adolescents between the ages of 10–15, i.e. before union of the epiphysis with the neck, which occurs about the 18–20th year. The patient is often of the fat, heavy type, with under-developed genitalia, suggestive of pituitary insufficiency. Enlargement of the sella turcica, as seen in a lateral X-ray picture of the skull, has been recorded.

The history is usually one of slight injury, such as a fall or twist of the leg whilst running. The child may get up and continue to walk or limp about subsequently. In some cases the condition is not discovered for some days, until there is pain, or a limp is noticed by the parents. On examination, there is adduction and external rotation of the affected limb, raising of the trochanter, and shortening of $\frac{1}{4}$-inch to $\frac{1}{2}$-inch. Movements are full except for abduction and internal rotation, which may be greatly limited. *A skiagram is essential for accurate diagnosis.* The lower lip of the epiphysis will be seen projecting below the lower border of the neck, the deformity being similar to that of an (adduction) sub-capital fracture in an adult. A notable feature is the absence of any bony spicule broken from the diaphysis, which is constantly present in slipped epiphyses in other situations (e.g. lower end of radius).

Should the case be of long standing, the displaced epiphysis will have fused with the femoral neck, the result being one form of *adolescent coxa vara.*

Treatment. This may be considered under three headings:

(1) *Within three or four weeks of the injury.*

(*a*) Reduction of the deformity under anæsthesia by manual traction, followed by abduction and fixation in a plaster spica ; or

(*b*) Reduction by continuous traction, exerted over a period of three months, until union is firm. The traction is combined with a gradual increase in abduction and internal rotation.

As the epiphysis is firmly engaged with the femoral neck, forcible traction may do no more than rotate the epiphysis in the acetabulum.

The method of reduction by continuous and gradual traction is much to be preferred.

When complete it may be continued until union is firm, or fixation may be effected by a plaster spica.

(2) *After four weeks* reduction will probably be impossible except by open operation, and fixation of the epiphysis by means of a bone peg or graft.

After-Treatment. Relief from weight-bearing by means of a caliper should be insisted upon for from 3-6 months after the initial period.

(3) *Late cases,* where union has occurred. Sub-trochanteric osteotomy should be performed in order to correct the coxa vara. Some shortening will be permanent. Limitation of movement at the hip joint is usual.

Prognosis. In *early* cases, when reduction and fixation has been satisfactory, the femoral head and neck may be expected to shape

normally. When reduction has been moderate, good function is to be expected for some years, but osteo-arthritis will develop subsequently. Open reduction is usually followed by a completely or partially ankylosed joint.

When reduction has been carried out by forcible manipulation and in some cases of non-reduction, the head will undergo the changes associated with deficient blood supply, and a stiff joint and early fusion of the head and neck will occur.

When reduction is imperfect, the epiphysis will often fuse with the shaft during the first year after the accident.

In *unreduced cases,* coxa vara will develop, and in later life osteo-arthritis is inevitable.

Early fusion of the epiphysis will result in shortening of the limb.

Shaft of the Femur

This group includes:

(1) Sub-trochanteric fractures.

(2) Fractures of the shaft proper.

The majority of cases occur in young adults and children. The type of fracture in adults may be either transverse or oblique, a common variation being the " butterfly " fracture, in which a triangular loose fragment becomes detached from the shaft. In children it is nearly always a long oblique or spiral fracture. Owing to the thick covering of muscles with which the bone is provided, open fracture is rare, but when it does occur, the consequences are likely to be serious owing to difficulty in maintaining accurate alignment during the longer period of union, which may result from: (*a*) Infection of the large hæmatoma and lacerated muscles; (*b*) osteo-myelitis and necrosis of bone; (*c*) delay in union, or non-union; or (*d*) stiffness of knee and ankle.

These fractures are usually accompanied by considerable shock.

Fracture of the Upper Third

The upper fragment is flexed by the ilio-psoas, and abducted and externally rotated by the gluteus medius, obturator internus and allied muscles. Control of the upper fragment is not possible, except by open operation, and it is necessary to remember that alignment must be obtained by bringing the lower fragment into a corresponding position.

Fracture of the Middle and Lower Thirds

Here, apart from the common factor of shortening or overlap, the adductor group is of importance (especially the adductor magnus).

The upper fragment tends to lie on the inner side of the lower fragment and often at an angle with it, the angle being open outwards (i.e. valgus).

Gravity is of considerable importance. Backward angulation of the fracture due to this cause is of frequent occurrence, both in the early and in the later stages of treatment.

Diagnosis is usually easy. The severe pain and shock, marked swelling, mobility, shortening and external rotation of the foot cannot be missed. The only cases likely to present difficulty in diagnosis are those of partial fractures in children, with a minimum of deformity, and these are rare.

X-ray examination *before* reduction of the fracture is desirable, but not always necessary, and may be omitted if not readily accessible. It should *never* be omitted *after* reduction, and in the majority of cases a portable apparatus is essential, because the patient and extension appliances cannot be moved into the X-ray room.

Treatment.

First Aid. Shock should be prevented as far as possible by keeping the patient warm. Ambulance attendants and others should be instructed that on no account must the patient be moved or lifted until a splint, possibly improvised, has been applied. The temporary splint of choice is a Thomas' provided with a large ring which can be slipped over the clothing. Fixed extension is easy to obtain by means of a clove-hitch over the boot, or a skewer thrust between the sole of the patient's foot and that of the boot. The extension is tied firmly to the end of the splint, the ring making counter-extension on the tuber ischii. The use of a Liston splint, so often applied as a first-aid measure, is bad. It is "better than nothing," but does not allow the application of extension which is so essential in the transport of these cases. The Thomas splint is easier to apply and far more effective. On arrival at hospital, the patient's general condition must be noted and treatment of shock, if necessary, should be carried out before the first-aid fixation is removed. A blanket bath or other exposure is to be avoided, as it is essential to keep the patient warm.

Reduction. Accurate reduction of a fractured femur can only be carried out by *traction*, which may be either:

(1) *Rapid.* (*a*) Manual; (*b*) Mechanical (screw-traction apparatus).

(2) *Continuously applied by means of a weight* through: (*a*) Adhesive strapping; (*b*) Skeletal traction appliances.

Manual traction is only applicable to children or adults with poor muscular development. When the method is to be used, it is best to apply the means of fixation of the fracture (i.e. adhesive strap-

ping) to the leg *before* traction is made. It is difficult otherwise to maintain traction and apply the strapping at the same time. When the traction has overcome all overlap, as checked by an assistant with a tape measure, a well-fitting Thomas splint is slipped on and the adhesive plaster tied firmly to the end of the splint. This method of *fixed extension* will maintain the degree of reduction already obtained, but in the event of incomplete reduction, no improvement in position will take place.

Should reduction be found to be incomplete, either by measurement or X-ray examination, some other method must be adopted.

Fixed extension is more suitable for children over the age of four, in whom it is usually easy to obtain complete reduction at the first attempt.

Screw traction should *not* be used for treatment of fractures of the femur, as a general rule. Its chief application is to the tibia, but in certain cases which are to be treated in plaster-of-Paris, the use of screw traction may be indicated.

Adhesive strapping: The chief applications for this method are in: (i) Children; (ii) Poorly-developed adults; and (iii) The later stages of treatment after the removal of skeletal traction.

Its usefulness is limited by: (i) The breaking strain of the material; (ii) Its adhesive power to the skin; and (iii) The amount of pull that may be applied to the skin without the development of sores.

In general, it may be said that 10 lb. is the limit of weight which can be used in conjunction with strapping, and as this weight is *insufficient* to reduce overlap of a fractured femur in a well-developed adult, the method of traction by adhesive strapping is a limited one.

The best type of strapping is *elastoband*—extension bandage (Smith and Nephew). This material is not expansile in the length of the strapping, but will stretch in width and therefore fits the limb.

Skeletal traction. The advantages, method, and sites of application have been considered in a previous section (see page 4395).

The Steinmann pin is recommended. If traction is to be made from the lower end of the femur, the pin should be used in preference to the wire as it is difficult to control the direction of a wire, owing to " whip " in the portion passing through soft tissue.

Site for traction (see fig. 2371).

The upper end of the tibia is usually advised, because it is:

(i) Accessible; (ii) Remote from the knee joint; and (iii) Remote from the hæmatoma surrounding the fracture.

Common sense must be used in the choice of site, but a pin inserted

through the lower end of the femoral shaft has the following obvious advantages: (i) A direct and better control of the lower fragment of femur is obtained. More powerful traction is possible. (ii) The traction is not applied through the ligaments of the knee joint, so that the risk of an *unstable* knee is avoided. (iii) The knee is left free for movement from the first. In spite of assertions to the contrary, the knee joint is *not* easily moved when the pin is placed in the tibia. (iv) Damage to the knee joint is inexcusable. It may be avoided by placing the pin in the lower third of the shaft and *not* immediately above the condyles. (v) Damage to the femoral artery is unlikely to occur if ordinary care is taken.

Direct contra-indications are: (i) Fracture in lower third (pin through site of hæmatoma); and (ii) Local sepsis or potential sepsis (i.e. an open fracture).

Anæsthesia. Deep general anæsthesia is required during the stages of insertion of the pin, manual traction, and adjustment of the splint. It is of great advantage to apply manual traction even if skeletal traction is to be used subsequently, as a large amount of overlap may be reduced when the muscles are completely relaxed. In Continental clinics, local anæsthesia is the routine method, but it seems better to reserve it for special cases in which the administration of a general anæsthetic is inadvisable.

Treatment of Fractures of the Femoral Shaft at different Ages

(1) *Birth injuries* to the femur are unusual, but may result from traction applied to the groin or leg during a breech delivery. The best method of fixation is to flex the thigh acutely on the abdomen and to maintain contact by means of a few turns of flannel bandage. Added support may be obtained, if required, by a moulded splint of metal or plaster, applied to the flexor aspect of the thigh and bandaged into position against the abdominal wall. Traction is not required. Fixation must be maintained until firm union is found upon clinical examination, usually a matter of 3–4 weeks. This method enables the baby to be suckled and his excreta to be attended to with little difficulty.

(2) *Children under five years of age.* The fracture is almost always oblique. The best method of traction is that of Bryant. Adhesive strapping is applied to both legs from groin to ankle. The child is treated on his back, with the lower limbs flexed to a right angle with the trunk. A Balkan beam or other bed frame is fitted to the cot and a cord from the injured leg passed over a pulley on the beam; sufficient weight is attached so that the child's buttocks are just clear of the mattress. The weight of the child's body acting through the site of

fracture is sufficient to bring about reduction. For the purposes of nursing it is convenient to tie the other leg loosely to the beam. Provided the knee of the sound leg can be flexed slightly, no interference with traction will result. The addition of back splints and foot-pieces to the fractured limbs helps the stability of the apparatus.

After four weeks, union will usually be firm enough to dispense with traction. The child should be kept in bed for another four weeks before weight-bearing is allowed, and it is usually advisable to apply a light plaster-cast during this period, for the sake of protection to the soft callus.

(3) *Children over five years of age.* These cases are best treated by "*fixed extension*" applied by means of adhesive strapping and using a Thomas splint of suitable size. The strapping should be applied down each side of the leg, extending from groin to ankle. No provision need be made for knee movements, as full movement will always be obtained at this age, provided accurate alignment has been secured. All overlap can be overcome by manual traction at the time of application of the splint, but should any persist, it is easy to tie a cord to the end of the splint and to apply a weight of 5 to 10 lb. This method of *combined* fixed extension and weight extension is perfectly rational. The "fixed" portion prevents any recurrence of overlap and the weight is used to overcome any that is not already reduced. All that is necessary is to take up any "slack" in the strapping (i.e. see that the ring of the splint is against the tuber ischii) by *daily* adjustments.

An added advantage is that the application of a small weight relieves the pressure of the splint ring against the skin of the buttock and so prevents chafing.

Note. With all extension apparatus a daily inspection is required. Spirit and powder should be "worked in" within the ring and at all pressure points, and care taken to see that the bandage slings on the splint are at the correct tension to prevent angulation. Special attention to the regions of the tuber ischii over the tendo Achillis and heel is advisable.

In from five to six weeks the splint may be removed or, alternatively, after three weeks, when the union is moderately firm, the leg may be put into a plaster-cast, including the pelvis and the foot.

In nearly every case this simple procedure can be carried out *without* an anæsthetic. The method is convenient as the child, once in plaster, can be sent home.

Weight-bearing should not be allowed for eight or nine weeks as a minimum.

(4) *Adolescents and adults.* In the majority of these cases, *skeletal traction* should be used as a routine (see fig. 2411). Counter-traction is

made by raising the foot of the bed 12 to 18 inches. A muscular patient will require a weight of 15 to 20 lb. at the outset, and during the first week X-ray checks should be taken on alternate days. The weight can be adjusted according to the X-ray findings. *Over-extension* must be avoided. At the end of a week, all overlap should be overcome and the

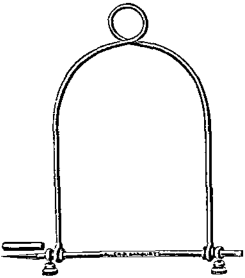

Fig. 2411.—Simple traction pin and stirrup. Note fixation screws to prevent the pin from sliding sideways. The stirrup is free to rotate on the pin, so that the pin does not rotate in the bone

optimum weight for maintenance of the fracture in good position should have been found.

The most useful splint is the Thomas. It should be provided with a hinged knee-piece, as shown in the illustration (fig. 2412). An adhesive strapping extension should be applied to the lower leg, and a small weight (5 lb.) added in the manner shown in the illustration. In either case, the knee should be slightly flexed so that the leg and foot are clear of the extension cord, which is in the line of the femoral shaft.

Having applied traction, the next step is to adjust the slings so that the normal forward bow of the femur is restored. The slings should be fastened with large safety-pins; the "paper clips" so often used are liable to slip gradually, thus allowing angulation to recur. The thigh and leg may be covered with flannel for warmth, and a "tea cosy" forms a suitable covering for the foot. All coverings must be readily removable for daily inspection.

Finally, provision must be made against *foot drop*. The best method is to attach a cord to the sole of the foot by a strip of adhesive plaster, and to pass the cord over a pulley. A small weight (1 lb.) pulls the foot up to a right angle and at the same time allows the patient to exercise the ankle.

Counterpoise. If a Thomas splint is used, the splint and leg

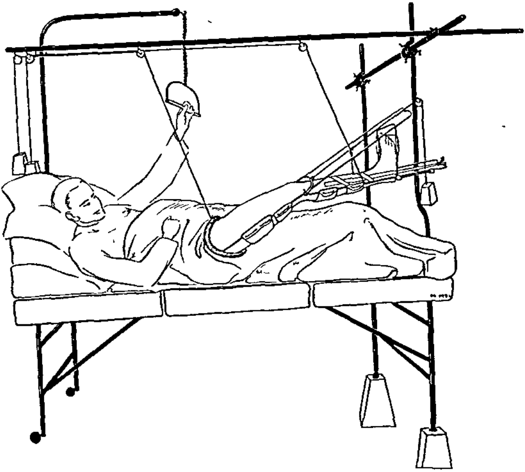

Fig 2412.—This diagram illustrates method of applying traction for fractured shaft of femur on a fracture bed.

Note traction pin in crest of tibia, weights to counterbalance splint and limb, hinged knee piece of Thomas splint, and support to keep foot at right angle. Foot of bed raised on blocks. Divided mattress is employed.

should be slung *clear of the bed* by means of a system of counterpoise weights. Two cords and weights are needed. One passes from the *splint ring over pulleys to the head of the bed. About 5 lb. weight should* be attached. This is enough to counterbalance the upper end of the splint when the patient is lifted for the purposes of nursing. The other cord is attached to the lower end of the splint and will need more weight (10 lb.) to balance the weight of splint and leg, so that it is kept clear of the bed. On no account should the splint be tied directly to the bed-rail.

Knee movements. Lateral movement of the patella is carried out from the commencement.

After four weeks, if union is progressing well, *passive knee movements* may be started. A "string and pulley" arrangement which enables the patient to do this himself is valuable.

Faradic stimulation of the *quadriceps* is a valuable adjunct until the

patient can learn to contract the muscle actively. This should be done for ten-minute periods, several times a day. The services of a masseur are necessary at this stage. The progress of union and position should be checked each fortnight by X-ray examination.

Removal of pin or wire. In the majority of cases, it is quite safe to leave the pin *in situ* for 6–8 weeks. If inspection of the site of the pin shows clean wounds, there is no reason why the pin should not remain in the limb longer. When the skin is removed, skeletal traction should be replaced by an adhesive strapping extension. Two sets should be applied, one set exerting traction in the line of the femur, the other in the line of the tibia—this may be applied when the primary setting is done—being fixed to the movable portion of the splint, and thus allowing knee movements to be continued. The strapping extension should be applied *before* skeletal traction is removed. Should suppuration appear at the site of the pin, it must be removed forthwith.

Usually at the end of 10-12 weeks traction may be relaxed and the splint removed. Some delay in union is common and the decision to remove apparatus must be made upon clinical and X-ray findings.

After-Treatment. Faradism and active exercises designed to strengthen the muscles and to increase the range of knee-flexion must be continued. A weight-bearing caliper must always be provided, and no weight-bearing should be allowed for at least another six months.

Difficulties in treatment.

(1) The surgeon is often asked to see "late" cases, which have been inadequately treated during the "all important" first week. Prolonged skeletal traction or open operation may be required to obtain a satisfactory result.

(2) Correction of *lateral displacement* is sometimes difficult. The use of sorbo-rubber pads, attached to a small clamp and screw which can be fixed to the bar of the Thomas splint, will usually overcome this difficulty. Lateral pressure can be applied by this means at the appropriate site. Lateral displacement seldom leads to such disability as follows unreduced antero-posterior displacement.

(3) Angulation is easy to correct by pads or by adjustment of the slings when there is no overlap.

(4) In cases of *delayed union*, the temptation to relax traction must be resisted. Traction *must be* continued until union is firm.

Delayed union may be brought about by excessive ardour on the part of the masseur or patient, or by over-extension. If sufficient rest and time be given, union will usually occur.

Late Complications.

(1) *Shortening* of more than ½-inch should be regarded as a bad result.

(2) *Stiff Knee*, due to:

(*a*) Prolonged fixation; or (*b*) Excessive callus formation in fractures of the lower third of the shaft. The quadriceps become adherent to the bone. Excessive callus means union in a bad position, and the complication will not occur in a well-aligned fracture.

(3) *Angulation.* This is due to inefficient treatment or to weight-bearing before the callus is consolidated. A badly-fitted caliper will allow it to occur.

(4) *Arthritis in knee and hip* may occur as a result of *malunion;* abnormal and excessive strain is thrown upon these joints.

Indications for Operations.

(1) *Early.* It is difficult to make out a good case for early operation in fractures of the femoral shaft, in view of the excellent results obtainable by skeletal traction. The risks of sepsis, delayed union due to internal fixation by foreign bodies, and the technical difficulties, are great.

Provided asepsis can be assured, however, operative fixation should still have a place for those cases in which skeletal traction has failed to obtain good alignment after ten days. Exposure of the shaft is made through an antero-lateral incision between the vastus externus and rectus muscles. Only the crureus need be incised. Plating is the best method of fixation, and a stout plate provided with eight screw holes should be used.

(2) *Late.* Cases of non-union or malunion may require open operation. *Bone-grafting with or without additional fixation* will probably be needed.

Treatment in Plaster-Cast.

Apart from children, the method has a very limited application owing to the impossibility of maintaining traction and to the prolonged fixation of joints which is inevitable. The method should be used for adults only in those few cases which are uncontrollable by other means. Mental derangement, lunacy, or when prolonged recumbency is undesirable, may be cited as examples. The cast must be applied while the femur is under traction on an orthopædic table, and should include the pelvis and the whole of the injured leg.

Supracondylar Fracture

It is important to realise that the lower fragment will be tilted *backwards* by the pull of the gastrocnemius. The sharp upper end of it may damage the popliteal vessels or nerves. *Genu recurvatum* will result if the deformity is not corrected.

Treatment is by skeletal traction, and the knee must be well *flexed.* A Thomas splint is used, bent at the site of the fracture. A pad behind the site of fracture may help to push the lower fragment into alignment.

Fracture of the Condyles

One condyle may be fractured from the shaft when the knee joint is forced into a varus or valgus position. Tear of the opposite lateral ligament may occur.

Both condyles may be fractured in falls upon the foot from a height. The upper end of the tibia is driven between the condyles like a wedge. The line of fracture is into the knee joint, and much effusion of blood into the joint will be present.

Treatment. (1) Manipulation may be tried. It should consist of traction on the leg by an assistant, while the surgeon exerts pressure on the condyles with his hands. If successful, the joint is fixed in a plaster-cast, extending from buttock to foot. The knee should be straight.

(2) More often, open operation will be required. A long lateral incision is made and the joint emptied of blood. The fragments are manipulated into position with bone levers, and fixed by bolts, screws or plates Gentle knee movements may be started in 3–4 weeks.

In either case after 6-8 weeks a weight-bearing caliper should be worn

Separated Epiphysis

Separation of the lower femoral epiphysis is an uncommon injury, but may occur before the epiphysis joins the shaft at about the twentieth year. The injury is one of hyperextension of the knee joint

Fig 2412.—Skiagram showing slipped epiphysis at lower end of femur. In this case a perfect reduction was obtained by manual traction.

so that the fractured surface of the epiphysis looks backwards (fig. 2413).

Treatment. This should be immediate manipulative replacement under general anæsthesia. Fixation may be in a plaster-cast with the knee flexed 20 degrees or, alternatively, the limb may be placed on a Thomas splint with extension. Should manipulation fail, skeletal traction must be made from the tibia. Knee movements may be started in four weeks, and a caliper should be worn subsequently.

PATELLA

The bone is fractured in two ways:

(1) *By muscular violence.* (Common in middle age.) The fracture is always transverse, about the middle of the bone, but may be nearer the upper or lower pole. It may be a crack, but commonly there is wide separation of the fragments, due to the action of the quadriceps muscles. It is important to realise that the line of fracture invariably extends sideways into the lateral patellar ligaments, which are part

Fig 2414.—(*a*) Illustrates separation of patella fragments with in turning of the aponeurosis. (*b*) Fibrous union joins the fragments in an untreated case.

of the extensor mechanism of the knee. The aponeurosis covering the bone is also torn, and the frayed edges curl in between the bone fragment (fig. 2414*a*), thus preventing bony apposition except by open operation. Fibrous union is certain to occur if the fragments are separated (fig. 2414*b*). The result is an unstable knee joint.

Rupture of the quadriceps tendon may take place instead of fracture of the patella (see also Vol. II, page 3462).

(2) *By direct violence.* This type occurs as a result of a direct blow on the patella. The fracture is stellate, and a minimum of displacement of the fragments is the rule.

Diagnosis. (1) Transverse type.

(*a*) History of having tripped, this being followed by pain. The patient attributes the accident to his subsequent fall. (*b*) Inability to extend the knee joint. (*c*) Great effusion into the joint. (*d*) A gap may be felt between the fragments; this may be masked later by blood clot and effusion. (*e*) X-ray examination.

(2) Stellate type.

The diagnosis is made upon the history of a direct blow, together

with local tenderness and effusion. In the skiagram a *bipartite patella* must not be confused with a stellate fracture.

Treatment.

(1) *Transverse or stellate types, without displacement.* A firm pressure-bandage is applied. The joint is immobilised in full extension on a posterior splint. It is best to mould a plaster slab to the limb, from the buttock to the ankle, but a wooden "Ham splint" forms a useful first-aid method of fixation. The limb is elevated upon a pillow. When swelling and pain have subsided, the patient may walk; after three weeks the splint may be removed daily for active exercises to the knee, but no walking should be attempted without it under six weeks.

(2) *Transverse type with separation of fragments.* The limb is elevated and a pressure-bandage and posterior splint are applied. The skin is carefully prepared for operation, which is usually undertaken four days after the injury.

The patella is exposed by a horse-shoe incision, convexity upwards; the incision should extend well laterally, so that adequate exposure of the lateral patellar ligament is made. The fragments are cleared of blood clot and aponeurosis, and excess blood is gently squeezed out of the joint. The methods of fixation of the fragments available are:

(*a*) A number of catgut stitches are passed through the aponeurosis covering the two fragments of bone and are pulled tight to approximate the fragments. The tear in the lateral part of the capsule is closed by catgut sutures. No suture passes through the bone.

(*b*) Each fragment is drilled vertically or horizontally and a

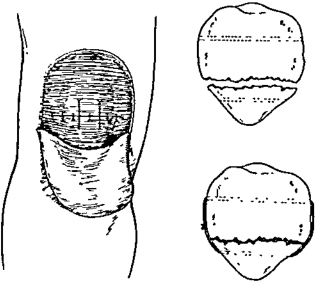

Fig. 2415.—Upper figure shows transverse fracture of patella with line of drill holes when placed horizontally. In lower figure fixation material has been passed and fragments drawn together tightly. Left hand figure depicts suture of aponeurosis and lateral portion of capsule. This may be employed alone, and is always the final stage of the fixation.

"mattress" suture of stout catgut or kangaroo tendon is passed through the holes. When tightened, the fractured surfaces should be in close apposition.

(c) A stitch is passed deep to the aponeurosis, and made to encircle the patella, like a purse-string.

In each case care must be taken that the articular surfaces are in accurate alignment. Careful suture of the layers of aponeurosis on either side and in front of the patella is next made, and the skin incision is then closed.

The first type of suture is suitable when the bone fits together easily and the aponeurosis is thick and takes the stitch well. The second type should be considered as the routine treatment. The stitch round the patella can be employed as an adjunct to either of the above methods or may be used alone. As a rule, it does not hold the transverse fracture well if employed alone.

(3) *Stellate fracture with spread of the fragments.* The operation employed is exposure of the patella, clearance of ragged tags of aponeurosis and encircling of the patella with a purse-string suture of thick catgut.

After-Treatment. A firm bandage and a posterior splint are applied over the dressings and the limb is elevated. The stitches are removed on the tenth day. The splint should be worn for six to eight weeks, and walking may be commenced after three weeks. Faradism to the quadriceps muscles is possible without removing the posterior splint. Active knee-joint movements are started in six weeks.

Complications.

(1) If silver wire is used as a suture material, sepsis and bone atrophy may necessitate its removal.

(2) Re-fracture is not uncommon. The other patella sometimes fractures during the period of convalescence.

(3) Some arthritis and stiffness of the knee is likely, as most of the patients with this fracture are middle-aged.

TIBIA

Fractures of the upper end of the tibia extending into the knee joint are of:

(1) The tibial spine.

(2) The condyles of the tibia.

The Tibial Spine

It is important to be aware of the existence of this injury, and to realise that the diagnosis is not difficult and that a definite line of treatment should be adopted immediately.

It is an "avulsion fracture," produced by violent tension on the anterior crucial ligament. As the latter is tense in extension, the violence is a forced *hyperextension* of the knee. The portion of bone torn up is usually about ½-inch wide, ¾-inch from before backwards, and ¼-inch thick. It is the area of attachment of the anterior crucial ligament. This portion of bone is elevated from its bed, so that it lies just above the level of the surface of the tibial head. The injury may occur in children under ten, but is most frequently seen in men between twenty and thirty. The history is that of a severe wrench. There is an effusion of blood into the joint, and pain at the line of the joint. The knee is locked so that full extension is not obtainable. With little displacement it will be locked at 170 degrees, but commonly at 150 degrees, so that the knee is 30 degrees short of full extension. There is abnormal antero-posterior movement so that the tibia can be displaced forwards on the femur. The antero-posterior skiagram shows a piece of bone in the joint, centrally placed, and this is seen in the lateral view also.

Differential Diagnosis. When there is little displacement, the lesion may be mistaken for a displaced semilunar cartilage owing to the locking. The skiagram will show the bony lesion. In an anterior crucial ligament tear alone, there is no bony block and a normal X-ray picture. In injury to articular surface of femur, tibia or patella, a fragment may be displaced and cause similar symptoms. The history in this type of case may not relate the exact type of violence. Bony block occurs, but laxity of antero-posterior movement is not present unless lateral ligaments have been torn. The X-ray film will show the hollow from which the piece of bone and articular cartilage have been detached.

Treatment. There is some divergence of opinion as to whether every case should be operated on to refix the detached piece of bone, or whether operation should be limited to those cases with considerable (¼-inch) upward displacement.

The *non-operative treatment* consists in manipulating the knee straight under an anæsthetic and fixing it in plaster. For such a manipulation to be a success it implies that the piece of bone is pressed back into its notch and remains there. In view of such an improbability, it is my opinion that this line of treatment should be limited to patients on whom an open operation is contra-indicated, or to those who realise that, if the post-manipulative X-ray photograph shows the displacement still present, an open operation will be necessary.

By *operative treatment*, a perfect reposition and a strong knee are

obtainable, whereas with the best manipulation the piece of bone is left *slightly elevated so that the anterior crucial ligament is looser than* normal. Removal of the fragment of bone is to be condemned.

Procedure. A tourniquet is employed. The knee is flexed 45 degrees from the extended position. The incision, which is nearly

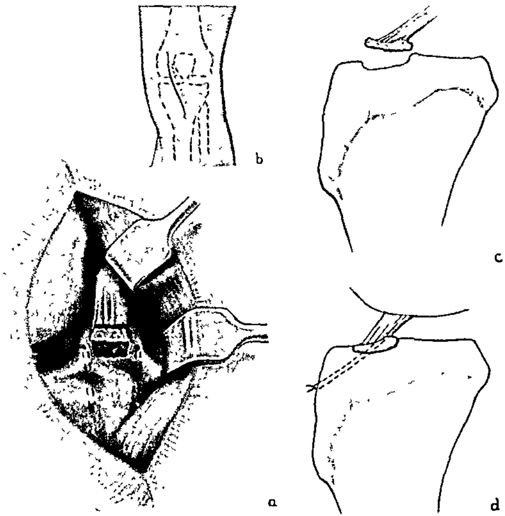

Fig 2416.—FRACTURE OF THE TIBIAL SPINE.

(*a*) Shows the fragment of bone elevated from the upper surface of the tibia. Line of drill holes are indicated.
(*b*) Line of skin incision used for exposure.
(*c*) Lateral view to show how fragment is elevated.
(*d*) Lateral view after replacement and fixation of fragment.

6 inches long, commences above on the inner side of the patella, ½-inch from its lower border, and extends downwards parallel to the inner border of the infra-patellar ligament to just below the tubercle of the tibia. The capsule and synovial membrane are opened in the same line. A retractor is placed on the infra-patellar ligament and, if free access to the front of the joint is not likely to be obtained, the tibial

tubercle is removed with a chisel, flush with the crest of the tibia, and the ligament and patella are retracted outwards. (This is unnecessary in a child.) With a dissector the edges of the fracture are defined and the fragment is carefully elevated. Blood clot and any loose cancellous tissue is removed from the notch. The fragment of bone is fitted into the notch.

Should the assistant elevate the leg, it will be seen that the fragment will leave the notch again.

With a morse drill not larger than $\frac{1}{16}$-inch, two drill holes are made from the anterior surface of the tibia, deep to the normal position of the infra-patellar ligament, obliquely upwards and backwards as shown in figure 2416. Catgut No. 2 threaded on a needle is passed up one hole, through the attachment of the crucial ligament to the fragment of bone and down through the second drill hole (alternatively it can be passed directly through the fragment, but drilling the fragment may split it). The assistant presses the fragment home with a pair of forceps whilst the stitch is tied in front of the tibia. The knee should now be extended to see that the fragment does not move. If this does occur, it shows that the stitches are too loose.

The tibial tubercle is fixed into place with stitches or a nail. The joint and skin are closed. The limb is put in plaster with an extended knee for ten weeks. Weight-bearing is allowed after a month, but no joint movement until the plaster is removed. A window can be cut for faradic stimulation.

The Condyles of the Tibia

The condyles are fractured by forcible abduction or adduction injuries of the knee (fig. 2417). The fracture line, of necessity, runs into the knee joint, and considerable effusion of blood will usually be found. Tearing of the corresponding semilunar cartilage is a frequent complication, particularly when the outer condyle is fractured. It may be displaced, so as to lie between the broken fragment and the fractured surface of the shaft.

Displacement. The triangular portion of condyle is displaced downwards, causing irregularity of the articular surface of the tibia.

Should the fracture remain unreduced, two serious complications are likely to follow: (*a*) Gross osteo-arthritis of the knee, with corresponding diminution in the range of movement; and (*b*) Genu varum, or valgum, according to the condyle involved.

Fracture of both condyles is a rare injury, but when it happens the tibial shaft is forced between them like a wedge.

Treatment. Should great effusion be present in the joint, it may be

wise to rest the leg for a few days on a Thomas splint, bent at the knee, or on a Braun frame. A firm pressure-bandage should be applied to limit the effusion.

Reduction.

(1) *By manipulation.* An anæsthetic is given and the knee strongly abducted, for fracture of the internal condyle. The internal lateral ligament remains attached to the fragments and pulls it upwards into

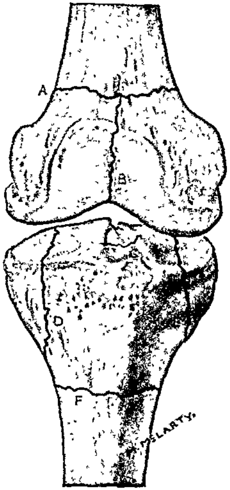

Fig. 2417.—Fractures of condyles of femur and tibia. Lines indicating the types occurring singly. The fracture of a condyle of the tibia may extend more into the centre of the joint than is here shown.

position. Direct pressure on the fragment (by the fingers) may be of assistance. The reverse manœuvre is applied for fractures of the external condyle.

(2) *Should manipulation fail,* a Steinmann pin is driven firmly into the fragment, which is then levered into position.

(3) *Incomplete reduction* should be treated by open operation. The fracture is exposed by a vertical curved incision, blood clot cleared away, and the loose fragment fixed by a couple of bone pegs or a wood screw. Removal of the corresponding semilunar cartilage may be necessary.

Needless to say, exceptional care must be taken that the skin of the operation area is intact, free from blisters, and carefully prepared by a three-day preparation. During the operation the knee joint is opened and the consequences of sepsis made correspondingly serious.

(4) *Fracture of both condyles* necessitates:

(*a*) Traction in the screw-traction apparatus from a pin through the os calcis.

(*b*) Lateral compression to force the displaced fragments into position, by the hands or by the compression clamp.

After-Treatment. The fracture having been reduced, the knee is fixed in a plaster-cast extending from the buttock to the toes. The joint should be in full extension but not over-extended, and care must be taken to avoid genu varum or valgum. Antero-posterior and lateral X-ray pictures are then taken as a check of accurate reduction.

A walking-iron may be applied and the patient allowed to get about after a week. The plaster should remain on for ten weeks.

Should it be decided to treat the case by massage and mobilisation, the cast should be bivalved after four weeks. Great care must be exercised, as the deformity is liable to recur, especially if weight-bearing is allowed too early without adequate support.

If traction fails to reduce the displacement, open operation is advisable. The fragments are aligned correctly and held in place by a metal screw and bolt. This is passed transversely about ½-inch distal to the joint. The advantage of the bolt is that, as it is screwed tight, the fragments are compressed. It is advisable to remove the bolt about eight weeks after the operation.

Shaft of the Tibia

The common site for fracture is in the middle third. Two types occur frequently: (1) The *transverse* fracture, due to direct violence and often associated with a skin wound; a large proportion of these result from motor-cycle accidents in young adults. (2) The *oblique* fracture, due to indirect violence or torsion. If a skin wound exists in this type, it is due to the sharp bony point of the lower fragment being forced outwards and not to the causative violence.

In children, the fracture is almost invariably of the *spiral* type, with little or no displacement. Fracture of the *fibula* is commonly associated. In the transverse type of fracture, the fibula is usually broken at or about the same level as the tibia. In the oblique type, the break in the fibula is 2 or 3 inches higher than the tibial fracture, but fracture of the neck of the fibula is often associated with fracture below the middle of the tibia.

Deformity. In adults, this is often considerable.

(1) *Transverse fracture.* (*a*) *Fibula intact*: little or no shortening; lateral displacement or angulation. (*b*) *Fibula fractured*: shortening and lateral displacement with angulation.

(2) *Oblique fractures.* (*a*) *Fibula intact*: angulation or lateral displacement. (*b*) *Fibula fractured*: shortening, in addition.

(3) *Spiral fractures in children* (*fibula often intact*): deformity usually limited to *slight* shortening and lateral displacement.

Complications.

(1) *Open fracture* is by far the commonest complication in adults. If the skin wound be a mere puncture, as it frequently is, many of these cases can be treated as if they were closed fractures, and run the normal course of a closed fracture. Should sepsis supervene, however, local osteomyelitis with sequestra formation will greatly delay the time of union.

(2) *Comminution* is frequently found in the transverse type due to direct violence. A triangular portion of bone may be detached or a number of smaller fragments may be present. Some may undergo necrosis, if torn from the attached muscle and periosteum.

(3) *Malunion* is seen more commonly than it should be. This may be attributed to faulty reduction, or to inefficient fixation for a sufficiently long period. Removal of the plaster-cast for "massage" before union is firm is another frequent cause.

The most serious cases of malunion are those with angular deformity. Slight shortening is of less importance. Sometimes a large, unsightly mass of callus forms around one of the detached fragments. Its presence is of no consequence except from the cosmetic point of view.

(4) *Non-union* results from: (*a*) Sepsis; (*b*) Over-traction with interposition of soft parts; (*c*) Insufficient splintage; and (*d*) Malposition.

Treatment.

(1) *Children.* Should displacement be present, correction under an anæsthetic by manual manipulation is usually all that is required. It is rare that the need for continuous traction arises. Fixation is by a well-fitting plaster-cast, extending from mid-thigh to the tip of the toes. The *knee should be flexed* 15 degrees, with the foot at right angles. Accuracy of reduction should be checked by antero-posterior and lateral X-ray films taken through the cast.

In small children it is well to protect the heel of the plaster with a pad of felt or to apply a wooden "sole" to the cast, otherwise the plaster will be found soft and cracked after a few hours of play by the child.

In older children a walking-iron may be fixed as soon as the cast is hard. In oblique fractures, however, the child should not bear weight on the leg for a month, as the risk of over-riding of the fracture inside the cast is great.

All splinting may be removed in from 6 to 8 weeks.

Note. It should be an *invariable* rule that *all* cases of recent fracture treated in plaster-of-Paris should be inspected within twelve hours of application of the cast. Better still if they can be admitted to hospital for twenty-four hours. Neglect of this precaution may result in pressure sores, swollen limbs, ischæmia or gangrene, apart from intense pain to the patient.

At the slightest suggestion of swelling or blueness of the extremities, the cast must be split open and the limb elevated. It is important to remember that wadding or bandage beneath the plaster should also be cut.

(2) *Adults.* Three methods are available:

(*a*) Manipulative reduction followed by plaster-cast.

(*b*) Reduction by means of the screw-traction apparatus of Böhler or Watson Jones, followed by plaster-cast.

(*c*) Continuous skeletal traction on a Braun frame for two or three weeks. Later, a plaster-cast.

(*a*) If the case is seen early, before much swelling has appeared, it is occasionally possible to " hitch " the fracture under an anæsthetic, and to fix it immediately in plaster. It is only possible to " hitch " transverse fractures in this way and the method is of limited application.

(*b*) Screw traction is particularly useful in oblique fractures. The essential points in the method are:

(i) The shortening is overcome by mechanical traction, and lateral displacement is corrected by pressure with the hands at the site of the fracture.

(ii) The knee is flexed to a right angle in order to relax the calf muscles. This is an essential step. Counter-traction is made by the bar of the apparatus against the lower part of the thigh, just above the popliteal space.

(iii) When reduction is satisfactory, a plaster-cast is applied and allowed to " set " *before* the traction is released (see Vol. II, figs. 1949 and 1950).

Method. The patient is anæsthetised, and the heel prepared and painted with iodine. A Steinmann pin is inserted through the os calcis, and a stirrup applied. An assistant makes manual traction from the stirrup, while the leg is lifted on to the traction apparatus. The bar for the knee must be well padded with felt or sorbo rubber, and should be adjusted to such a height that the knee, when resting upon it, is flexed nearly to a right angle. The stirrup is attached to the hook of

the traction screw. It is convenient to have a spring balance between stirrup and hook, so that the actual traction may be read off in pounds, but this is not essential. The screw is gradually tightened, and a careful check is kept upon the measurement of each tibia (from the upper end to the internal malleolus. Both legs should be in the same position while the measurement is taken.) If the fracture can be "screened" in the theatre, so much the better.

When all shortening has been overcome, the site of the fracture is massaged in order to remove any œdema, and the subcutaneous surface of the bone is palpated. Any lateral displacement is corrected by pressure with the two hands from either side.

The leg, if hairy, is smeared with vaseline to prevent adhesion of the plaster.

A plaster slab is made, 6 inches wide and of sufficient length to extend from the knee to the toes, as measured along the back of the leg. It is applied directly to the skin, without padding, and bandaged along the calf with smooth turns of flannel bandage. That portion for the foot is now moulded round the heel and cuts are made at the corners to make it lie smoothly. The foot portion should be held by an assistant until hard. The corners may be made quite strong by splitting the layers of plaster and dovetailing them together alternately.

When correctly applied, there should be a strip of skin uncovered by plaster, about 2 inches wide down the front of the leg. A thin layer of wadding is now laid over this gap in the plaster. Finally, two or three plaster bandages are applied in the ordinary way so that the whole leg from knee to foot is encased. When the plaster is set, traction is released and the apparatus removed. The knee is now protected by wadding and the cast continued up to the middle of the thigh. The pin is removed through a small hole in the cast.

The position of the fracture is checked by means of X-rays. When this method is used, the patient may walk in a few days with a walking-iron fixed in the plaster.

Modifications.

(i) It is sometimes recommended that a complete plaster-cast be applied without the preliminary slab and wadding. If this is done, it is *essential* to split the cast immediately along the anterior surface throughout its whole length, as considerable swelling of the limb may occur after screw traction is released.

(ii) Instead of carrying the cast above the knee, a firm hold on the upper fragment may be obtained by inserting a second pin through the upper end of the tibia. In this case both pins are left *in situ* and

incorporated in the plaster. As an alternative to the pin through the os calcis, one may be placed through the lower end of the tibia.

(c) *Continuous traction.* This should be used:

(i) Where screw traction has failed. (In this case the plaster slab is not applied, but the fractured limb is immediately transferred to a Braun frame and continuous traction applied.)

(ii) As an alternative to screw traction.

(iii) Where the fracture is complicated by a large wound or by sepsis.

(iv) In late cases, in which deformity has not been corrected at the outset.

Method. The patient is anæsthetised, a pin is inserted through the os calcis, and a stirrup then applied.

The limb is laid upon a Braun frame and a weight of 10–15 lb. attached to the stirrup. After a few days a set of X-ray films is taken and any necessary adjustment made. Special care is taken that the limb is not over-extended and, when shortening has been overcome, the weight is reduced. Usually in from 3–6 weeks the callus is sufficiently firm to allow the application of a plaster-cast. This should be applied in the manner already described, but the layer of wadding may be replaced by one turn of flannel bandage. The slab should be applied *before* traction is released, the slings on the Braun frame being removed for the purpose. When hard, the limb is lifted clear of the frame, stirrup and pin are removed, and the plaster-cast is completed.

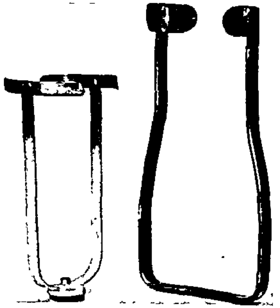

Fig. 2418.—Two types of walking iron or stirrup. The rubber pad is a Phillips rubber heel, attached by a bolt.

Should a wound be present, "an inspection window" may be cut in the plaster.

After-Treatment. The majority of these fractures should be treated by the "ambulatory method" and a walking-iron fitted as soon as the cast is hard (fig. 2418). Patients can walk quite satisfactorily after a little practice, even when the knee has been included in the plaster. The use of crutches should be discouraged, but one or two stout walking-sticks are necessary as a precaution against falls.

With elderly or feeble patients it is difficult or impossible to carry out ambulatory treatment, and the wiser course is to "bivalve" the cast as soon as union is firm and to treat by massage, movements, and assisted exercises.

The time necessary for complete union varies enormously. Closed fractures in healthy young adults should be firm in three to four months, but manual labourers rarely return to work under six months.

Lower Third of the Shaft of the Tibia

A common fracture, due to indirect violence, is at the junction of the middle and lower thirds of the tibia. This oblique fracture—termed *flute en bec*—is associated with a fracture of the neck of the fibula.

Displacement usually occurs and consists of angulation, rotation, and overlap with little lateral displacement.

Reduction by manipulation is not satisfactory. With skill, skeletal traction with a posterior slab may produce complete reduction in perfect position. It is often difficult to control the tendency of the lower fragment and foot to rotate.

This fracture is one in which a perfect end-result can be achieved by an open reduction, carried out preferably a few days after the injury. The approach is easy, and the bones can be replaced accurately and fixed by a six-screw Lane's plate, placed on the surface of the tibia facing the fibula. If the plate is placed on the subcutaneous surface, it will have to be removed later. The use of a plate is preferable to that of a band, more accurate and firmer than wire, and a simpler procedure than a bone graft. The limb is put into a light plaster. This is changed when the stitches are removed, in order to get a more tightly-fitting plaster over less wool. *Weight-bearing is not allowed for eight weeks.* Splinting is usually advisable for twelve weeks from the date of operation. As a rule, callus formation is neither rapid nor extensive after this operation.

In children, a partial fracture of the tibial shaft, about 2 inches above the ankle joint, is often seen, the fibula being fractured at the same level.

Deformity consists of considerable angulation in the antero-posterior plane. Manual correction under an anæsthetic is usually easy.

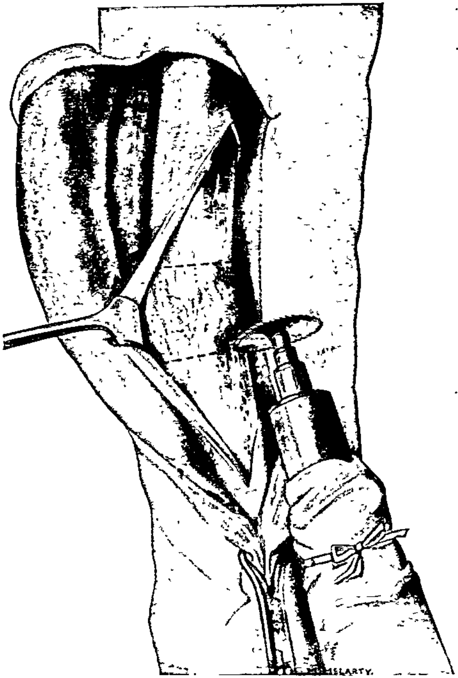

Fig. 2419.—Bone graft of the tibia for fibrous malunion. The site of fracture has been exposed, and the periosteum retracted. The dotted lines indicate the line of division of the bone with the saw.

(1) *Greenstick fracture.* If some form of fixation is not employed, a lump of callus due to the subperiosteal hæmatoma will form which is sufficient to worry the parents. A pad of felt should be placed over the site of the fracture and fixed by strapping. The arm is put in a sling and kept within the child's clothing for three weeks.

(2) *Fractures of the shaft.* The weight of the arm assisted by the pull of muscles attached to the outer fragment will cause the outer fragment to be displaced downwards, inwards and forwards. The inner fragment seldom moves.

Treatment. When displacement exists and the fracture is seen within forty-eight hours, reduction should be carried out. An anæsthetic is not required. The patient is seated in a chair and the forearm is supported by an assistant. The shoulders are grasped and drawn outwards, backwards and upwards. Pressure over the fragment is seldom helpful.

Fixation is required for a month. A pad of felt is fixed in place over the fracture with elastoplast. The method recommended is the "handkerchief method" or some modification of it. The simplest arrangement is the loose application of a triangular bandage round each shoulder. A pad of wool or felt should protect the axillæ. The ends of these bandages are tied firmly at the back between the scapulæ, so as to pull the shoulders back, and the arm is supported in a sling. A broad bandage holding the arm to the thorax should be worn at night. The objection to this method is that the bandages tend to get loose and the knots at the back are uncomfortable.

An equally efficient and comfortable modification consists in the use of two 6-inch flannel or domette bandages. A loop is made round each shoulder with the end of the bandage. The end is fixed to the length of bandage by two safety-pins over the scapula. The long end of each bandage is then grasped and pulled so that the shoulders are drawn backwards. The ends are crossed in the centre of the back and carried round the chest to be tied in front. The arm is supported in a sling.

There are ample reasons for the avoidance of Sayre's method which is commonly employed and is described in detail in most surgical text-books. The firm fixation obtained or the interest in its application may be reasons for its frequent use, although the discomfort of it is considerable. In consequence of the band round the arm, veins are obstructed and swelling and œdema occur. The extensive covering of the limb with adhesive plaster frequently causes a dermatitis and hair follicle infection. There is an unnecessary fixation of the elbow,

wrist and hand, which is painful, and massage and joint movement cannot be carried out without removing half the fixation.

Two other methods of treatment should be known, as the practitioner may have to treat either type of case. If the patient is anxious to avoid the possibility of any *visible deformity* and is prepared to remain in bed, the deformity should be reduced, even under anæsthesia if necessary. and she should lie in bed on her back. A flat sand-bag is placed vertically between the scapulæ for three weeks. The arm on the affected side is abducted to a right angle from the body and fixed by a roller towel and sand-bags. A low pillow is used and a divided mattress for use of the bed-pan.

A rather reverse line of treatment is adopted in the case of those who are anxious to continue *active use* of their arm in spite of the fractured collar-bone. It is suitable for jockeys, but those using their arms above their shoulder level should not be treated on these lines. A felt pad and strapping are applied over the site of the fracture, and a sling is worn. Radiant heat and massage are employed to cause absorption of the hæmatoma. The shoulder muscles are kept in good condition by faradism. Union will occur, but deformity is usual. A second fracture calls for greater fixation, as non-union may result.

The fixation by bandages round the shoulder, attached to wooden or metal splints applied to the back, keeps the shoulders back but is not comfortable or necessary.

Complications. Injury to the brachial plexus or to the subclavian vein is extremely rare. A case of non-union is periodically reported, and operative treatment may be required under such conditions.

Prognosis. Full functional result is obtained almost invariably. Although the outline of the bone may not be anatomically perfect and its length may be shorter than normal, the use is normal. Operative treatment is sometimes required for the complications mentioned, or for removal of a spike of bone protruding and uncomfortable owing to the braces rubbing the skin overlying it.

(3) *Interligamentous fracture* is uncommon. If displacement is present, it is reduced by placing one hand over the shoulder and inner part of the clavicle up against the neck, whilst the other hand grasps the elbow and pushes up both this and the shoulder.

When there is no displacement, the arm is placed in a sling for three weeks. At the end of that time exercises above the shoulder can be carried out.

If there has been displacement, or the shoulder is dropped and uncomfortable, a pad of sticky felt, 4×3 inches wide, is placed over the

site of the injury. A calico bandage, 4 inches wide, is passed round the padded elbow and carried vertically upwards and tied over the felt so as to force the elbow up. The free ends of the bandage are passed over the chest, one in front and one behind, so as to tie off in front of the axilla on the sound side. Adjustments may be required during the three weeks this is worn, and a sling alone will be required for a subsequent week.

SCAPULA

The types of fracture are:

(1) The *body* is broken by direct violence, such as a crush.

(2) The *acromion process* is injured by a fall on the back of the shoulder.

(3) The *neck of the scapula* and *glenoid fossa* are fractured by a heavy fall on the shoulder and arm.

(1) *Fracture of the body.* Comminution is often present, and displacement is prevented by the supporting muscles. There are signs of local injury and often dyspnœa. Other injuries frequently necessitate the patient being in bed. When this is the case, the arm should be placed in a sling, and heat and massage employed. The patient should be placed in a sitting posture, and if well enough to be up, relief will be obtained by encircling two-thirds of the chest with broad elastoplast and supporting the arm in a sling.

(2) *The acromion process* is rarely injured. The outer fragment may be tilted downwards, and the diagnosis of dislocation of the acromio-clavicular joint be made until the skiagram is seen. The treatment is similar to that of interligamentous fracture of the clavicle.

(3) The *neck of the scapula* may be fractured:

(*a*) Through the neck, including the coracoid process in the smaller fragment, or

(*b*) Into the glenoid fossa.

(*a*) This is rare. The signs are: the shoulder is flattened, there is pain on shoulder movement, the acromion and outer end of the clavicle are in normal relationship, and there is tenderness at the apex of the axilla. The X-ray film shows the body of the scapula to have been displaced towards the axilla. In a heavy woman with a large shoulder, the arm should be put in a sling, and radiant heat and massage be employed immediately. Active movements with assistance should be commenced in ten days. In a young patient with normal physique, an attempt at reduction may be employed. This consists in fixation of the axillary border of the scapula with one hand, and forcible pushing up of

the shoulder with the other hand. Fixation is on the same lines as that for *interligamentous* fracture of the clavicle.

(*b*) *Fracture of the glenoid* is usually seen as a complication of subcoracoid dislocation of the shoulder. The diagnosis in an uncomplicated case is unlikely to be made from clinical examination alone, as the signs and symptoms are those of a fracture into the joint. However, when a dislocated shoulder re-dislocates quickly after reduction, and crepitus is palpable, the glenoid is likely to have been fractured.

The arm should be placed in abduction, 90 degrees from the trunk. This can be done by plaster, which will necessitate an anæsthetic, or by a metal abduction splint. An X-ray picture should be taken to ensure that the head is not dislocated during the splinting. Movement of the fingers, wrist and elbow is encouraged. After three weeks, the arm is placed in a sling and physical treatment employed.

Prognosis after scapular injuries. After fractures of the acromion and body of the scapula, hard work should be possible with full function in eight to ten weeks. After fracture of the neck of the scapula most patients obtain full movement even when anatomical alignment is not perfect. Limitation of rotatory movement and full extension may occur, and although most occupations can be followed in three months, heavy work will not be undertaken until later.

Fracture through the glenoid is a more serious accident, and full movement, particularly above the shoulder, is unlikely to be obtained.

NECK OF THE HUMERUS

Types. (1) With no displacement.
(2) Adduction fracture.
(3) Abduction fracture.

Stereoscopic X-ray pictures are often necessary for an exact diagnosis, as a lateral view is seldom obtainable.

Type 1 (see fig. 2374—No. 1). There is a crack across the surgical neck of the humerus, and the great tuberosity is usually comminuted but not separated from the shaft. The fracture occurs only in adults, and is produced by trauma applied to the outer side of the shoulder.

The treatment consists in: (*a*) Placing in the axilla a pad of wool 6 inches square and 2 to 3 inches thick (depending on the size of the patient). The axilla is washed with spirit, dried and powdered. The wool pad is covered with gauze to prevent the wool flaking off. (*b*) Binding the arm to the side with a 6-inch bandage. (*c*) Placing the arm in a sling.

If swelling and pain are considerable, heat and massage can be

employed immediately. Bruising may extend downwards to the elbow. After three days pain is slight, and the pad and bandage can be left off and the arm kept in a sling. Active exercises, especially abduction and external rotation, should be commenced and practised

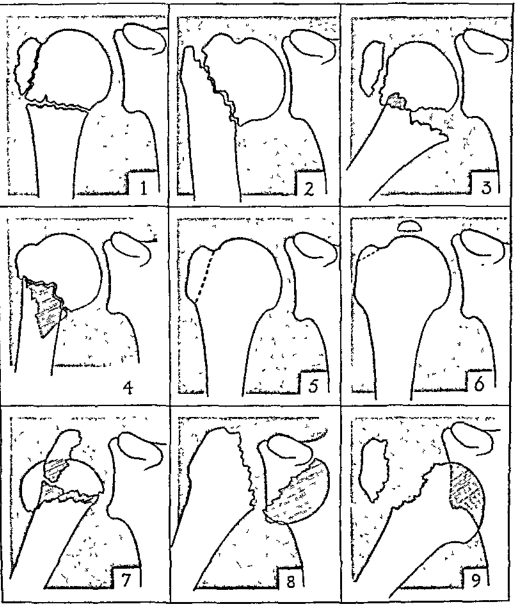

Fig. 2374.—Diagram of fractures and fracture-dislocations of the neck of the humerus.

1. Humeral neck crack and fracture of great tuberosity.
2. Oblique fracture of neck.
3. Fracture of neck and tuberosity with displacement.
4. Fracture of the neck in childhood (separated epiphysis).
5. Fracture of tuberosity.
6. Avulsion fracture, showing displacement of that portion of tuberosity to which supraspinatus muscle is attached.
7. Fracture dislocation. Impaction with lateral displacement of the head.
8. Fracture-dislocation. The head is in the position of a subcoracoid dislocation.
9. Fracture dislocation. The great tuberosity is fractured. The head, not broken from the shaft, is in the position of a subcoracoid dislocation.

frequently for ten minutes at a time. The forearm, hand and fingers should be used as much as possible.

A full range of movement should be obtained in two to four months. Difficulties only arise owing to prolonged immobilisation. If the arm is immobilised for a number of weeks, adhesions occur in the capsule between the humerus and lower part of the glenoid so that abduction and external rotation are limited and painful. Pain usually persists over the front of the joint. Such a condition is seldom relieved by physio-therapeutic measures alone, and manipulation under an anæsthetic is required to regain movement.

Type 2 (see fig. 2374—No. 2). There is an oblique fracture extending through the lower part of the great tuberosity downwards and inwards. The tuberosity is not separated, and there is often impaction of the inner part of the fracture. The injury is caused by a fall on the outstretched hand, the limb being carried inwards (adducted) at the moment of the impact. The fracture is most common in elderly patients and often in heavy women. If the fracture is impacted, the treatment is identical with that of Type 1. If it is not impacted, pain is usually greater, and the movement between the fragments can be felt by the patient and examiner whenever the elbow is moved. The fragments will soon adhere together, and release from the chest bandage and commencement of active exercises should not be delayed longer than one week. The sling should be left off as soon as possible and certainly not be used all day after a month. Some limitation of abduction and external rotation is frequent in elderly patients but is not considered a severe disability by them. An anæsthetic, manipulation, or prolonged fixation is undesirable.

Type 3 (see fig. 2374—No. 3). There is a transverse or slightly oblique fracture (upwards and inwards) through the top of the humeral shaft, and the great tuberosity is separated from the head. There may be a slight displacement of the shaft inwards, with outward and backward rotation of the head, with or without impaction; or, the upper end of the shaft may lie in front and to the inner side of the head.

The fracture results from a fall on the outstretched hand when the arm is straight and away from the body. The treatment and prognosis cause greater anxiety than in the case of Types 1 or 2. When the fracture is across the shaft, the treatment is easier than when there is a spike on the inner part of the shaft.

If there is little displacement and impaction, no manipulation is advised. Otherwise, an anæsthetic is given and the displacement corrected. Traction is applied to the arm in an adducted position (i.e.

arm across the chest) and pressure is applied to the top of the shaft by a hand in the axilla. This is directed to replace the fragment or impact it into the head. A pad is placed in the axilla, and the limb is fixed to the side for three weeks. Radiant heat and massage can be employed to relieve pain, without removing the bandage. After three weeks a sling is used and active movements are encouraged. Faradism to the muscles round the shoulder may be helpful.

When there is little displacement of the fracture, good function is obtained after the manipulation. If no reduction is attempted, or failure to correct the deformity results from the manipulation, there is invariably limitation of abduction, external rotation, and extension. An elderly patient is more likely to complain of pain in the shoulder than of permanent limitation of movement. Therefore, the question may arise as to whether further attempts at reduction and fixation should be employed. In the middle-aged patient this is advised. An abduction splint—such as holds the elbow away from the side—should be avoided, as further abduction of the shaft on the head of the humerus may occur and the end-result be one of considerable limitation of abduction.

Improvement in alignment is sometimes obtained by putting the patient to bed, with an extension on the arm. A splint similar to a Thomas thigh splint is employed. This should not be kept on for more than three weeks. The elbow should be moved daily after ten days, the extension being released for this purpose, unless a double fitting is added to the splint. I have not seen difficulty in the arm coming to the side after this method of treatment, but a stiffness of the elbow is inevitable in an adult if it is fixed for a number of weeks. Operative treatment is not required; removal of the head of the humerus is followed by great weakness of all movements at and above the level of the shoulder, so that a patient cannot take a book from a shelf above the level of the head. Jones' arm splint with extension bands over the metal bars beyond the elbow is not comfortable when used for the treatment of this fracture.

After union or malunion, the X-ray appearance is no criterion of the function of the shoulder.

Fracture of the neck of the humerus in children (see fig. 2374—No. 4). This is caused by a fall on the outstretched hand when the arm is in front of the body, or rarely by a fall on to the shoulder.

It is almost invariably of the adduction type. The fracture line is extraordinarily constant; the head of the humerus, the cartilaginous plate, and a wedge-shaped piece of the outer part of the metaphysis form the upper fragment. If there is displacement there may be (*a*)

impaction on the inner side with crushing, or (*b*) displacement of the shaft forwards in an adducted position.

When there is no displacement, the treatment is straightforward —a pad in the axilla, and fixation of the arm to the side for three weeks, and then in a sling for three weeks. Early movement may cause displacement and is of no advantage as a child or adolescent will readily regain movement.

When there is displacement, an anæsthetic should be given and the deformity corrected by traction on the arm, which should be held at an angle of 45 degrees from the side of the body. Pressure on the outer side of the head of the humerus will help in the correction. Sometimes reduction can be accomplished by traction with the arm across the chest. A pad is then placed in the axilla and the case treated as if there were no displacement. A skiagram of the shoulder should be taken to ascertain whether the position is satisfactory. If this method of correction fails, a decision must be made whether to leave the deformity or to correct it by open operation. The latter consists in exposing the fracture on the outer side, placing the fragments in position, and fixing the arm to the side. Internal fixation by a plate, screw, etc., is seldom required, as it is usually possible to produce and maintain a perfect or nearly perfect position without its help. However, if the shaft is left in front and to the inner side of the epiphysis, it will unite, but the humerus will be short in adult life owing to the union with overlap and premature disappearance of the epiphysial plate. There is likely to be a shelf at the top of the shaft for two years or more, with slight alteration in the appearance of the shoulder, but full function. I have seen a subluxation of the sterno-clavicular joint follow a malunion of the upper end of the humerus in a girl of thirteen, possibly owing to her zeal to regain full movement quickly.

This fracture with displacement should not be treated in abduction on an abduction splint. In a few cases the shaft, before it is "gummed" on to the epiphysis, will sink downwards so that the fracture becomes an abduction fracture, and the elbow is held away from the side when the arm is removed from the apparatus.

Fracture of the Great Tuberosity (*uncomplicated*).

This may consist: (1) of a comminution of the whole tuberosity with little or no displacement, or of a separation of the whole tuberosity (see fig. 2374—No. 5), either of which is caused by a direct blow or fall; or (2) of a slight or complete avulsion of the portion of the tuberosity, into which the supraspinatus muscle is inserted (see fig. 2374—No. 6). This is due to traction injury.

In either type, when there is *no displacement*, the arm is placed in a sling, which is worn continually for two weeks. After that time, the patient is encouraged to do without it as much as possible. Heat and massage are employed from the date of injury, the elbow and wrist being used throughout. Active exercises can be commenced in three days, when the immediate pain has disappeared. Adhesions are particularly liable to form if the shoulder is immobilised, and active movements will be painful and restricted if the shoulder is moved by a masseuse.

Although this appears to be a trivial fracture, pain and stiffness often last for some weeks, and full movement with freedom from discomfort may not occur for two and a half to four months.

When there is *displacement*, it is necessary to bring the bony fragment in contact with the humerus, for the deltoid cannot abduct the arm more than 45 degrees from the body, unless the supraspinatus is active as a fixation muscle for the head of the humerus.

Treatment therefore consists in placing the arm in an abduction frame, in a position of 90 degrees abduction and external rotation, so that the hand is above the head. This position must be maintained for eight weeks, during which time the fingers, wrist and elbow must be exercised. At the end of that time, the arm is gradually brought to the side and is kept in a sling for two weeks. If the apparatus permits, faradic stimulation of the deltoid can be employed during the weeks of immobilisation in the splint.

This small fracture leads to disability—viz. weakness of abduction and all overhead movements, unless the fragments are approximated. In view of the discomfort of the apparatus it is reasonable to advise the patient that by operative means the length of time the arm is out of action can be shortened. Such a procedure is definitely advisable if the fragment has been allowed to remain displaced for ten days. The operation consists in exposure of the fragment and its fixation in the normal position by means of a small bone peg or screw driven through it into the head of the humerus. Firm fixation is thus possible and, after ten days, treatment will be carried out as if there was a fracture with no displacement.

FRACTURE-DISLOCATION OF THE SHOULDER

Type 1. There is a fracture, usually oblique, at the upper end of the humerus with dislocation of the head of the humerus out of the glenoid fossa. When the fracture is impacted, the great tuberosity is usually broken off, and the head displaced laterally into the top of the broken shaft. (See fig. 2374—No. 7.) In the unimpacted type, the head tears

the capsule and comes to lie in the subcoracoid area. This serious injury results from a fall on the outstretched hand when the arm is abducted. The treatment is difficult.

The impacted fracture. Manipulative reduction is usually possible, owing to the firm fixation of the bones. If it is successful, the head remains on the outer side of the top of the shaft. Disimpaction of the shaft from the head generally results in aseptic necrosis of the head, and is not advisable. In elderly patients, in those whose general health contra-indicates operation, and in left arms, the patient is prepared to accept disability; in such cases it is advisable to put the arm in a sling and employ physio-therapeutic methods without delay. The end-result will provide the patient with not more than 50 per cent of normal movements. Movements below the shoulder level are not likely to be painful. Complete ankylosis of the joint does not occur if early movement is employed. In younger and fitter patients, open operation is advisable. The joint is exposed by means of an anterior incision through the deltoid muscle. The head is disimpacted and the parts inspected with a view to fitting them together. There is comminution of the cortex of the upper end of the shaft, so that exact reposition is difficult. The choice rests between impacting the head on to the shaft in correct alignment and fixing the great tuberosity lower down than its normal situation, or fixing the head into the shaft by an intramedullary peg or graft. Satisfactory results may follow either of these procedures if carried out soon after the injury, but a successful end-result is sometimes marred by aseptic necrosis of the head, due to gross injury to the blood supply to the head. Such a complication usually leads to complete, or nearly complete, ankylosis, or painful arthritis may follow.

The unimpacted fracture (see fig. 2374—No. 8). Manipulation under anæsthesia is indicated. The head of the bone is located and one hand placed on it. With the other hand, traction is applied to the arm drawn across the chest. It is gradually carried outwards whilst firm pressure is made on the head. If that fails, the arm is carried further outwards and upwards so that traction is applied with the arm above the level of the shoulder. Successful reduction is more likely to follow if it is carried out soon after the injury. The arm is fixed to the chest for three days and is then placed in a sling; exercises, heat and massage are employed.

Failure of reduction necessitates open reposition of the head by an operation on the lines already indicated.

Type 2. The great tuberosity may be fractured, or the supraspinatus avulsed as a complication of subcoracoid dislocation of the

humerus. (See fig. 2374—No. 9.) Such a complication occurs in one-third of all shoulder dislocations. When the tuberosity is fractured from the shaft, it is usually found that after reduction of the dislocation there is little displacement. A large pad is placed in the axilla, and the arm is fixed to the side for ten days. Radiant heat and massage are employed on the shoulder, active exercises are encouraged, and the arm is placed in a sling. Full movement is seldom obtained in elderly patients and the period of disability is often as long as six months.

Complications of Shoulder Injuries.

Stiffness and *ankylosis* of the joint occur in consequence of some of the injuries described even after the most efficient treatment. They are more likely to form in elderly patients and when there has been an effusion of blood in the joint for some period. The means of prevention are early treatment of dislocation and fracture, accurate replacement of bone, early active movements and the avoidance of passive movements.

Nerve injury complicates dislocation frequently but fracture seldom. Fracture-dislocation causes a somewhat greater number than either lesion. The circumflex nerve paralysis or paresis is as frequent as all the other nerve injuries combined. Posterior cord lesions affecting the triceps and wrist and finger extensors, as well as the deltoid, are next in frequency. The diagnosis is usually made two to three weeks after the initial injury, probably because the muscle weakness is considered to be the result of bruising only. Permanent paralysis is very rare.

Circumflex paralysis (affecting the deltoid muscle) usually recovers in three to four months. Treatment consists in relaxation of the affected muscle by splinting, and in electrical stimulation. In deltoid paralysis, an abduction splint should be employed. If this is contra-indicated by the bone or joint injury, the latter must receive the primary consideration for two weeks.

SHAFT OF THE HUMERUS

Fracture of the shaft usually results from direct violence. It is not common in children, except through a cyst in the upper third of the shaft. In adults it is seen in the upper third and across the middle of the shaft. In the latter situation, it is usually a transverse fracture with a notch in one fragment and a spike on the other. In the upper and lower thirds a long oblique fracture generally occurs, and quite frequently there is one fragment broken off, which is often 3 inches in length. Doubt about diagnosis does not occur and the exact injury is seen in the skiagram. The muscles of the forearm and hand should be tested in order to appreciate at the outset if there is any nerve

involvement, such as musculo-spiral paralysis. The general principles of treatment are those applicable to a fracture of the shaft of any long bone, viz.:

(1) Early and accurate setting under an anæsthetic.

(2) Firm fixation.

(3) Early movement of those parts not fixed in the splinting—in this case, of the wrist and fingers.

Three facts are outstanding: first, the request that the fracture may be treated without confinement to bed; secondly, the difficulty of employing a comfortable method of fixation; and, thirdly, the periodic occurrence of non-union of transverse fractures of the middle of the shaft of the humerus, with formation of a pseudarthrosis.

There is seldom any reason for treating a fractured humeral shaft in bed, provided the general condition is good, but elderly patients are often better in bed for a few days. The other points are considered appropriately below.

The routine treatment consists in an anæsthetic for the setting. A Jones splint is employed, elastoband or strapping extension is placed on the inner and outer surfaces of the arm, and oblique narrow strapping fixed over this (fig. 2375). The axilla is powdered and the splint applied. The ends of the extension bands are tied round the notches, a strip of metal is placed to keep the vertical bars equidistant, and the forearm is rested in a trough of flannel bandage. The arm is adjusted until it is thought to be straight. One or two short wood, metal or plaster splints are placed round the arm and a flannel band is passed round the inner vertical bar and pinned to the outer bar.

A skiagram is then taken to check the position, and readjustment made if necessary, care being taken that the fragments are not separated. This apparatus is not very comfortable, particularly in bed. The greatest comfort is obtainable by the patient sleeping with a back-rest, the splint being placed outside the pillow and back-rest. The forearm should not be drawn across the chest or abdomen; this is not only uncomfortable, but rotates the lower fragment. Swelling of the elbow usually occurs. The axilla must be cleansed with spirit and powdered. Adjustment of the extensions is not often required. In the case of a transverse fracture, this splint should be worn until there is radiological evidence of good callus formation. In oblique fractures the fragments adhere together quickly, and non-union never occurs. It is usually safe after three weeks to remove the splint, and to make a posterior plaster trough for the forearm and arm and a short anterior

splint. These can be fixed round the arm with webbing and buckles and removed for physical treatment. Short splints round the arm itself are required during the last few weeks of fixation, which is often necessary for as long as eight weeks in transverse fractures.

Complications. A fracture through a cyst of the upper third of the humerus is seen in children. As a rule, the fracture is the first evidence of the cyst. Although such a cyst diminishes in size after the hæmorrhage into it from the fracture, it seldom disappears altogether, so

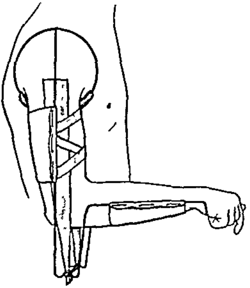

Fig 2375.—Jones' arm splint. Extension is applied to the arm. The forearm is shown pronated, which is more comfortable than supinated, but supination movements should be employed.

Fig 2376.—Skiagram showing fracture of the humerus with one loose fragment. Typical fracture complicated by musculo-spiral paralysis.

that it is advisable to expose the cyst, remove the contents, and splint the arm to ensure a cure.

Fracture of the lower third of the humerus is complicated by injury to the *musculo-spiral nerve* in a number of cases. Usually the fracture is oblique and there is a spike on the top of the lower fragment (fig. 2376). When the paralysis is incomplete, it is reasonable to splint the arm and to employ electrical treatment for the muscles. If the injury has been a bruising of the nerve, quick recovery may ensue. If there is no recovery or increased paralysis in three weeks, the case should be treated on the same lines as a complete paralysis recognised at the time, namely, by operative treatment.

The incision should be sufficient to expose the nerve above and below the site of the supposed lesion, together with the whole length of the fracture. It is usually convenient to make the incision along the anterior border of the brachio-radialis, and to extend it upwards and curving slightly round the back of the arm at the level of the musculo-spiral groove. The nerve should be exposed above and below the supposed lesion and traced up and down gradually until the lesion is found. The nerve is protected whilst attention is being paid to the bone. This should be accurately aligned and the fragments fixed together by the method to which the surgeon is most accustomed—plating, pegging, or such-like. A piece of triceps is then sutured over the fracture. The nerve is sutured or treated as appears necessary (see Vol. II, page 3471) and placed in the new bed protecting it from the bone. Flexion of the elbow is advisable to prevent tension of the nerve. A light plaster trough is applied. After-treatment for the fracture and nerve is on the lines indicated in Vol. II, page 3480. Injury to the brachial vessels or to the median or ulnar nerve is rare in association with simple fractures of the shaft of the humerus.

LOWER END OF THE HUMERUS

Injuries of this region are common and, although a great variety exists, a definite grouping of types is possible:

(1) Supracondylar fracture.
(2) Fractures of the internal epicondyle.
(3) Fractures of the external condyle.
(4) Complicated fractures.

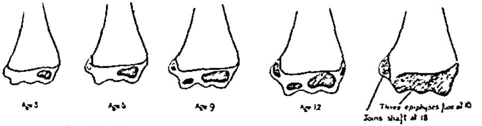

Fig. 2377.—Mode of ossification of epiphyses of lower end of humerus.

The first three groups occur almost entirely in children, usually under the age of twelve. Falls on the elbow or on the hand which cause these injuries in children frequently result in fractures of the head or neck of the radius in adults. Examination of an elbow before swelling has occurred shows the position of the bony points—olecranon and epicondyles—which is information of clinical importance, but they are quickly concealed by swelling. Radiography provides exact information,

as lateral and antero-posterior views are easy to take and to interpret if one has an accurate knowledge of the normal shape and ossification of the lower end of the humerus (fig. 2377). Such information is obtained, not only from a knowledge of anatomy but from studying skiagrams of the part at different ages. The average ages of ossification of the epiphyses are indicated in the diagram. The dates are liable to variation and those quoted are rather later than is common in this country.

(1) *Supracondylar Fracture* (fig. 2378, A and B)

The *line of fracture* is obliquely upwards and backwards from the epiphysial line, so that a portion of the shaft is on the distal fragment.

A B

Fig 2378.—SKIAGRAMS OF SUPRACONDYLAR FRACTURE OF HUMERUS WITH BACKWARD DISPLACEMENT AND TILT. A. BEFORE REDUCTION. B AFTER REDUCTION

If there is *displacement*, it is upward and backward, often with lateral or medial displacement. Anterior displacement is rare, and rotation may occur in any case.

Treatment. (*a*) When there is no displacement, the arm is fixed in as full flexion as is compatible with safety to the vessels, by one of the methods described later.

(*b*) When there is displacement, an anæsthetic is given. The elbow is extended and the forearm supinated; if the fracture does not feel loose, the deformity is increased, and firm traction is applied to the forearm, *whilst the elbow is gradually flexed. During this procedure the other* hand makes pressure on the *front* of the lower end of the humeral shaft. The extent of flexion should be such that there is no interference with

the flow of blood through the brachial artery, which can be detected by feeling the radial pulse, or with the venous return through the veins in front of the elbow.

Fixation is made by elastoplast round the wrist and the upper end of the forearm and by placing the arm in a sling which prevents the angle between forearm and arm being altered.

The radial pulse is again felt, in order to make sure that the circulation is satisfactory.

The elbow is inspected next day and, all being satisfactory, the method of fixation is not changed for three to four weeks (the longer period for the older child). The elbow is then placed in a sling for a week and the child is told to touch the shoulder frequently so as to keep up the flexion. Extension will come back by usage. Exercises are not necessary, and the carrying of weights may be harmful. Massage and passive movements must not be employed.

Alternative methods of fixation are numerous. The "collar and cuff" fixation of the wrist to the neck is popular, but has the disadvantage that the child's forearm usually becomes pronated immediately after the setting and varus deformity may result.

By perfect setting and fixation and rest, a perfect result is anticipated.

Forward displacement is reduced by traction and pressure on the fragment in the antecubital fossa. Methods of fixation and after-treatment are similar to those employed for the common fracture.

Difficulties and Complications.

(*a*) *Excessive swelling of the elbow* and blistering of the skin of the antecubital fossa occur in a proportion of cases. They are most frequent when the arm is left untreated for a few days, when unnecessary force has been employed in setting the fracture, and when several attempts have been made at reduction. This complication is particularly common when the setting is faulty. The treatment is by avoidance of the causes. When swelling has formed, care must be taken that the flexion is not so acute as to interfere with the circulation. The blisters should be treated by sterile puncture, and by the application of powder and a strip of boracic lint which should be left in the fold of the elbow until the part is dry and the swelling subsiding.

(*b*) *Imperfect reduction* may be: (i) persistence of some backward displacement, or (ii) lateral displacement.

(i) When the fragments are hitched and there is no backward tilting, it is often advisable to leave the fracture in this position, although there is not a perfect anatomical position. When the fragments have joined, there is somewhat of a beak at the lower end of the

shaft at the site of the fracture. This will absorb after a number of years.

(ii) If lateral or mesial displacement is not corrected, alteration in the carrying angle will occur. Failure to correct mesial displacement will produce cubitus varus—gunstock deformity—whereas persistence of lateral displacement causes an increase in the carrying angle. Persistence of these deformities may necessitate osteotomy of the lower end of the humerus a few years later.

(c) *Nerve injuries.* The median nerve is sometimes injured by pressure of the lower end of the shaft upon the posterior aspect of the nerve. This may occur when the backward displacement is great, or when too forcible hyperextension is employed in reduction. The sensory loss usually affects the distal two-thirds of the first and second fingers, while the motor paralysis involves the thenar eminence and the median lumbrical muscles. Recovery occurs, as a rule, in three months, but may be delayed for a year. Very rarely are the musculo-spiral and ulnar nerves affected in supracondylar fracture.

(d) *Volkmann's ischæmic contracture.* This rare complication is not likely to occur if early and accurate reduction is carried out. The early symptoms may commence a few hours after interference with the circulation, and consist of pain and numbness of the fingers and hand. The fingers are discoloured early and lose voluntary movement. The treatment is considered on page 4384.

(e) *Myositis ossificans* is discussed on page 4381. Although it may commence soon after forcible manipulation or massage, symptoms do not arise for three weeks. The essential treatment is rest by placing the arm in plaster-of-Paris. Early operation should not be performed. Small areas of bone will absorb, but weeks or months of rest may be necessary. If bone absorption is incomplete and a series of skiagrams taken at monthly intervals shows that the new bone is remaining unchanged, it is advisable to remove the plaque of bone causing obstruction.

(2) *Fractures of the Internal Epicondyle*

These are essentially fractures of childhood, occurring about the age of twelve. The epiphysis alone is usually separated, but a small flake of diaphysis may be adherent. The fracture results from a forcible abduction of the forearm on the arm, and it may complicate a dislocation of the elbow joint.

Type 1. A small chip may be torn off, or the epicondyle may be fragmented, without displacement. The treatment consists in flexion of the elbow for three weeks, followed by active exercises.

the flow of blood through the brachial artery, which can be detected by feeling the radial pulse, or with the venous return through the veins in front of the elbow.

Fixation is made by elastoplast round the wrist and the upper end of the forearm and by placing the arm in a sling which prevents the angle between forearm and arm being altered.

The radial pulse is again felt, in order to make sure that the circulation is satisfactory.

The elbow is inspected next day and, all being satisfactory, the method of fixation is not changed for three to four weeks (the longer period for the older child). The elbow is then placed in a sling for a week and the child is told to touch the shoulder frequently so as to keep up the flexion. Extension will come back by usage. Exercises are not necessary, and the carrying of weights may be harmful. Massage and passive movements must not be employed.

Alternative methods of fixation are numerous. The "collar and cuff" fixation of the wrist to the neck is popular, but has the disadvantage that the child's forearm usually becomes pronated immediately after the setting and varus deformity may result.

By perfect setting and fixation and rest, a perfect result is anticipated.

Forward displacement is reduced by traction and pressure on the fragment in the antecubital fossa. Methods of fixation and after-treatment are similar to those employed for the common fracture.

Difficulties and Complications.

(*a*) *Excessive swelling of the elbow* and blistering of the skin of the antecubital fossa occur in a proportion of cases. They are most frequent when the arm is left untreated for a few days, when unnecessary force has been employed in setting the fracture, and when several attempts have been made at reduction. This complication is particularly common when the setting is faulty. The treatment is by avoidance of the causes. When swelling has formed, care must be taken that the flexion is not so acute as to interfere with the circulation. The blisters should be treated by sterile puncture, and by the application of powder and a strip of boracic lint which should be left in the fold of the elbow until the part is dry and the swelling subsiding.

(*b*) *Imperfect reduction* may be: (i) persistence of some backward displacement, or (ii) lateral displacement.

(i) When the fragments are hitched and there is no backward tilting, it is often advisable to leave the fracture in this position, although there is not a perfect anatomical position. When the fragments have joined, there is somewhat of a beak at the lower end of the

(3) *Fractures of the External Condyle*

These fractures are uncommon, representing less than 1 per cent of all fractures. They are more common in children than in adults, and result from indirect trauma. In children, the mechanism of fracture is adduction of the forearm with the elbow incompletely extended, the strain producing an avulsion of the fragment from the humerus.

Type 1. In *adults*, the piece of bone broken off consists of the capitellum, part of the trochlea, and a piece of non-articular bone above and behind the articular area. There may be no displacement or forward displacement with rotation of the fragment. The exact diagnosis is of importance, as the fracture extends into the joint and a small displacement disturbs the normal joint mechanism. If there is no displacement, the elbow is put at rest at a right angle in a posterior plaster trough. Displacement is an indication for open operation. The joint is opened on the outer side so as to expose the lower end of the supracondylar ridge, the fractured piece of bone and the head of the radius. Blood clot is cleared away and the fragment rotated into place. In most cases fixation is not required, but if the fragment does not remain in place, it must be fixed by catgut passed through a drill hole made in the diaphysis, or a bone peg (one-eighth of an inch in diameter) may be driven transversely through the fragment to fix it to the trochlea. The elbow is put at rest for three weeks, after which active exercises are commenced.

Type 2. In *children*, the fractured piece consists of the capitellar epiphysis (the capitellum and half the trochlea) and a thin flake of diaphysis, off the back of the lower end of the humerus (see fig. 2380). When there is no displacement, the elbow is flexed and the case treated like *a supracondylar fracture with no displacement*. When there is displacement, manipulative reduction is seldom successful and open operation is necessary or else non-union of the fragment and cubitus valgus will result. The extent of exposure has been indicated. The fragment will be found to be rotated and lying often in the soft parts, owing to a tear of the muscular aponeurosis overlying the condyle. The lateral ligament is not torn and acts as a hinge on which the fragment rotates. The fragment is rotated into position and some form of fixation is necessary to prevent its lateral displacement; a catgut stitch usually suffices and a peg or nail should be avoided, as such a foreign body is likely to interfere with epiphysial development. Active movements are commenced after three weeks' fixation. Normal elbows are obtained after efficient reposition.

Complications. If the fragment is not rotated and fixed into its normal position, the lower end of the humerus will develop into an abnormal shape. The inner side will grow and the outer side be stunted, while the capitellar epiphysis will grow into a somewhat mushroom-shaped mass separated from the humerus. Cubitus valgus will be present and the arm will be weak. Later in life, ulnar neuritis or paralysis will develop owing to the tension of the nerve as it passes round the internal epicondyle of an arm with cubitus valgus.

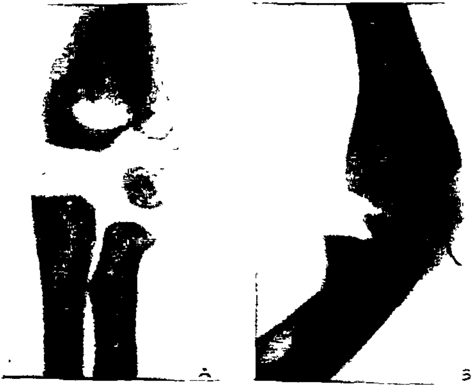

Fig. [illegible].—Radiograms showing fracture of the capitellar epiphysis with a flake of diaphysis. The fragment is displaced and rotated.

Type 3. External epicondylar fractures are isolated and uncommon. There is pain and tenderness. Union will occur if the muscles are relaxed.

(4) *Complicated Fractures of the Lower End of the Humerus*

This group includes T and Y fractures, which may occur with or without dislocation. Comminution o [illegible] , of the elbow joint occurs sometimes, commonly with fr [illegible] . Usually there is gross deformity and it is imp [illegible] fragments by manipulation. Recently attem [illegible] obtain alignment by skeletal traction applic [illegible]

At the onset it must be realised that full elbow movement is seldom obtained, but 90 degrees of movement is usually possible if early operative treatment is undertaken. Osteo-arthritis does not occur to such an extent as after a comparable fracture into the knee joint. The operative procedure should aim at:

(*a*) Reposition of all large fragments.
(*b*) Fixation by extra-articular means, whenever possible.
(*c*) Removal of small fragments.
(*d*) Enlargement rather than diminution of the joint space by the operative procedure.

The best incisions are placed laterally, and the surgeon should have the care of nerves and vessels in mind.

These principles are carried out in T and Y fractures by seeing that no small fragment is impeding an accurate placing together of the articular cartilage at the lower end of the humerus. The fixation is carried out by screws, wires or a plate, placed extra-articularly. The mechanical method employed must depend on the surgeon's experience with such means of fixation.

A comminuted fracture of the capitellum, the head of the radius, and the olecranon with posterior dislocation may be seen after heavy falls. This is best treated by open reduction of the dislocation, fixation of the olecranon, and removal of the fragments of bone from the outer side of the joint. A large and clean gap should be made between the top of the radius and the lower end of the humerus. Such a procedure may leave an arm with over 100 degrees of painless movement. After operation of this type, the arm should be placed in a plaster trough for a month, shoulder and finger movements being encouraged from the outset. Then heat and active exercises can be started, the patient wearing a more tightly-fitting trough which can be removed daily for treatment. After six to eight weeks, a sling is substituted. Passive movements and massage are prone to produce ossification in ligaments and muscles round the joint and should be avoided.

FRACTURES OF THE RADIUS AND ULNA WITHIN THE ELBOW JOINT

Such injuries are usually caused by falls on to the elbow, but a fall on to the outstretched hand may produce an injury to the head or neck of the radius.

These fractures are classified together to remind the practitioner that the fracture is within the confines of the joint and that therefore the prognosis is liable to be more serious than after fractures of the shaft. From the point of view of diagnosis the common features are pain,

Complications. If the fragment is not rotated and fixed into its normal position, the lower end of the humerus will develop into an abnormal shape. The inner side will grow and the outer side be stunted, whilst the capitellar epiphysis will grow into a somewhat cubical-shaped mass separated from the humerus. Cubitus valgus will be present, and the arm will be weak. Later in life, ulnar neuritis or paralysis will develop owing to the tension of the nerve as it passes round the internal epicondyle of an arm with cubitus valgus.

Fig. 2380.—Skiagrams showing fracture of the capitellar epiphysis with a flake of diaphysis. The fragment is displaced and rotated.

Type 3. *External epicondylar* fractures are isolated and uncommon. There is pain and tenderness. Union will occur if the muscles are relaxed.

(4) *Complicated Fractures of the Lower End of the Humerus*

This group includes T and Y fractures, which may occur with or without dislocation. Comminution of the bones of the elbow joint occurs sometimes, commonly with fracture of the olecranon. Usually there is gross deformity and it is impossible to assemble the fragments by manipulation. Recently attempts have been made to obtain alignment by skeletal traction applied through a wire in the olecranon.

At the onset it must be realised that full elbow movement is seldom obtained, but 90 degrees of movement is usually possible if early operative treatment is undertaken. Osteo-arthritis does not occur to such an extent as after a comparable fracture into the knee joint. The operative procedure should aim at:

(a) Reposition of all large fragments.
(b) Fixation by extra-articular means, whenever possible.
(c) Removal of small fragments.
(d) Enlargement rather than diminution of the joint space by the operative procedure.

The best incisions are placed laterally, and the surgeon should have the care of nerves and vessels in mind.

These principles are carried out in T and Y fractures by seeing that no small fragment is impeding an accurate placing together of the articular cartilage at the lower end of the humerus. The fixation is carried out by screws, wires or a plate, placed extra-articularly. The mechanical method employed must depend on the surgeon's experience with such means of fixation.

A comminuted fracture of the capitellum, the head of the radius, and the olecranon with posterior dislocation may be seen after heavy falls. This is best treated by open reduction of the dislocation, fixation of the olecranon, and removal of the fragments of bone from the outer side of the joint. A large and clean gap should be made between the top of the radius and the lower end of the humerus. Such a procedure may leave an arm with over 100 degrees of painless movement. After operation of this type, the arm should be placed in a plaster trough for a month, shoulder and finger movements being encouraged from the outset. Then heat and active exercises can be started, the patient wearing a more tightly-fitting trough which can be removed daily for treatment. After six to eight weeks, a sling is substituted. Passive movements and massage are prone to produce ossification in ligaments and muscles round the joint and should be avoided.

FRACTURES OF THE RADIUS AND ULNA WITHIN THE ELBOW JOINT

Such injuries are usually caused by falls on to the elbow, but a fall on to the outstretched hand may produce an injury to the head or neck of the radius.

These fractures are classified together to remind the practitioner that the fracture is within the confines of the joint and that therefore the prognosis is liable to be more serious than after fractures of the shaft. From the point of view of diagnosis the common features are pain,

swelling of the joint, and limitation of movement with local tenderness; whereas extravasation of blood is usually extensive after a fractured olecranon. it may be absent after a fractured head of the radius. Bleeding into the joint is common to all these injuries.

The group consists of:

(1) Fractures of the radius—(*a*) head: (*b*) neck.

(2) Fractures of the ulna—(*a*) olecranon; (*b*) coronoid process.

(1) *Fractures of the Radius.* These occur nearly four times as frequently as injuries to the outer side of the lower end of the humerus. Of 3000 consecutive ambulatory fractures, the head of the radius was

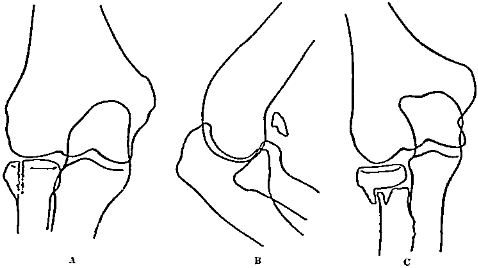

Fig. 2381.—A. Vertical fissure fracture of head of radius. B. Fracture of head with displaced fragment. C. Fracture of neck with rotatory displacement.

fractured in 124, and the neck in 37. whereas the capitellum and external epicondyle were fractured in 45. The average age of the "head" injury was 22 and that of the neck 14.

(*a*) Fractures of the *Head of the Radius* are of three types:

(i) A vertical fissure, descriptively termed a "chisel fracture" (fig. 2381A).

(ii) A fracture with one loose fragment (fig. 2381B).

(iii) Comminution of the head, including the mushroom fracture.

(i) and (ii). The diagnosis of either of these injuries will remain in doubt until a skiagram is taken. When little or no displacement occurs. treatment consists in full supination and flexion. This is possible if the patient is seen shortly after the injury, but if the joint is allowed to swell before treatment is commenced, it will only be possible to flex the elbow to a right angle or so. By use of a collar and cuff or special

sling, the extent of flexion will be increased by daily adjustment. This position is retained for four weeks, and then for one week the elbow is in a sling at a right angle. After that, flexion and extension exercises are commenced. Good function is present in eight weeks, but full function is often not obtained for four months.

(ii) When one loose fragment is displaced, this should be removed by open operation. The ideal time for this is within one week of the injury. It is carried out through an incision on the outer side of the joint. At operation, further fissuring of the head is sometimes seen. This may involve articular cartilage only, and when no displacement is present other than of one fragment the operation should be limited to removal of the fragment.

(iii) The comminuted fracture is a more serious injury than the two already described. The several fragments are separated so that the total circumference of the head is increased and rotary movement greatly limited. The treatment consists in removal of the head and part of the neck of the radius. The best results are obtained by primarily putting the arm at rest at a right angle in a sling for six weeks. Then operation is carried out. This has two advantages: that ossification of the capsule will occur neither before the operation nor following it. Formation of small spicules of bone and thickening of ligaments are the usual causes of limited movement after early removal of the radial head. The disadvantage is that there is a six-weeks' delay for the patient, but the end-result is worth the delay. After the delayed operation, a full range of movement is sometimes obtained, but the usual end-result is permanent limitation of 20 degrees of extension with a full range of other movements.

The operation of removal of the head of the radius is carried out through an incision in the line of the forearm from the external epicondyle downwards. As the lower end of the incision should not be as distal as the point where the posterior interosseous nerve winds round the radius, it is often advisable to extend the incision upwards.

The aponeurosis of the extensor muscles is split in the line of its fibres and retracted. The capsule is picked up at the level of the capitellum and incised in the line of the incision down to the neck of the radius. The head of the radius is now exposed. Blood clot is removed if present. If the head is loose, this is removed and the upper end of the shaft trimmed. If the head is joined to the shaft, a half-inch chisel is used to cut through the neck about a quarter of an inch distal to the head. The stump is trimmed with bone forceps. The synovial membrane and aponeurosis are closed in separate layers. After closure

of the skin, the arm is placed for three weeks in a light plaster trough extending from the axilla to the wrist. After that interval active movements are instituted.

(*b*) *Fractures of the Neck* are usually transverse and just below the head, but a wedge-shaped piece of bone is frequently detached from the shaft with the " head fragment."

In the case of children (for this injury occurs between the ages of six to twelve) the line of fracture is distal to the cartilaginous plate through the top of the shaft. In one-third of these cases there is displacement.

Treatment. With little or no displacement, the condition is treated as if there were a fissured fracture of the head of the radius.

Displacement may consist of: (i) a tilt; (ii) rotation of the head and neck on the shaft (see fig. 2381c); (iii) the head being alongside the shaft, or removed away from it, even to the inner side of the forearm; or (iv) comminution and displacement.

Operative treatment is indicated in:

(i) and (ii). In these cases, it is necessary to make the decision as to whether a better elbow will be obtained by leaving the bone to join with the deformity or by operation. This is a difficult decision to make. At the time of the examination soon after the injury, the range of movement is limited not only by the mechanical obstruction due to the displacement, but also by spasm of muscle and effusion into the joint. Hence the X-ray appearance is the principal help in the decision. In patients over fifty years of age, the case will be treated by immobilisation in as full flexion as possible for three weeks. In younger patients, a small degree of tilt or rotation will be treated similarly, but a tilt to the ulna, a 30 degree tilt in any direction, or a rotation through more than 45 degrees (often shown by the wedge-shaped piece of bone on the neck) are indications for operative treatment, as a manipulation will not correct these deformities. The operation will consist of an exposure of the head of the radius and of the line of fracture. The displacement is corrected, and frequently a slight impaction will hold the fragment firm. Complete rest for three weeks is advisable before active movements are commenced.

(iii). Manipulative reduction of a displaced head is seldom successful. It is more likely to be possible a few hours after the injury than later. I have seen two repositions in children but none in an adult. Hence it can be given a trial, with the realisation that it may fail. If there is failure, operation should be carried out within one week of the injury. The outer side of the joint is exposed, as has been described for removal

of the head of the radius. It is essential to use a tourniquet, and a pneumatic one is the safest.

The head is located, and care taken not to tear any periosteum or capsule which may be adherent to the neck or fragment. The upper end of the shaft is cleared of clot, but not trimmed. The head is replaced. It is usually possible to tell by spicules of bone around the edge of the head and neck how the head should fit on. If the head can be slightly impacted into the neck, this is carried out. Additional help in fixation may be possible by passing catgut through any soft tissue adherent, or by two drill holes distal to the articular cartilage through which a stitch can be passed. The forearm should be pronated and supinated to ensure that the head is not displaced by these movements.

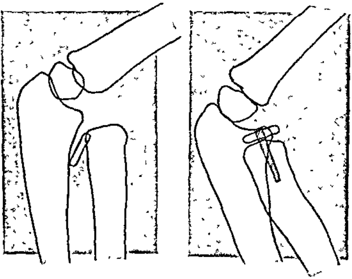

Fig 2382.—A. Fracture of the neck of the radius in childhood (separation of the epiphysis) with displacement. B. Open replacement and fixation with centrally placed bone peg.

After closure, splinting is employed for two to three weeks, after which active exercises are started.

In the case of children, fixation is more difficult. It is carried out by driving a bone peg through the articular surface of the head and up the shaft, so that at the end of the operation the peg is entirely extra-articular (fig. 2382). There is a minimum of damage to articular cartilage. In children, owing to the temporary separation of the head from its blood supply, the X-ray picture will show changes in the epiphysis subsequent to replacement. After a number of months, re-consolidation of the epiphysis will occur and usually the bone peg is absorbed.

Removal of the head of the radius should be avoided in a child, as it may be followed by cubitus valgus of an extreme degree and complicated by limited wrist movement, radial deviation of the hand, and

prominence of the head of the ulna. The operation in an adult is discussed later.

(iv) When the head is comminuted and displaced, removal of all the fragments and trimming of the upper end of the shaft is indicated. My own preference is to put the arm at rest and to remove the mass of bone some weeks after the injury.

(2) *Fractures of the Ulna.* (*a*) *The olecranon process* may be fractured transversely or there may be a stellate or comminuted fracture. It is caused by a fall or blow on the point of the elbow. When there is no separation, there is tenderness and bruising with pain on flexion and extension. In the case of separation. the diagnosis is made easy by the gap which can be felt between the two fragments.

Treatment. When there is no separation and in elderly patients, a light plaster trough is bandaged to the back of the arm and forearm, the elbow being placed at a right angle During setting, pressure is applied to compress the olecranon down on to the shaft as far as possible. This is not removed for three weeks. It is then taken off for exercises, but worn for six weeks altogether. This position is employed because the arm is very uncomfortable when left for three weeks with the elbow straight and because there is swelling of the hand. If the splinting is applied early, no separation occurs in the cases with no traumatic separation, and in elderly patients with separation this can be largely overcome. A stellate fracture is treated in a similar manner. When there is a transverse fracture with separation in a patient otherwise fit, open operation is advisable during the first week after injury.

The incision should be planned so that the scar is on the posterior part of the arm and the outer surface of the forearm. Half-a-horseshoe-shaped incision is suitable, the top of the incision being 1 inch above the olecranon. The fracture is exposed and blood clot removed. The aponeurosis, which is turned in over the fractured surface, should be elevated so that the bony fragments can be brought into accurate apposition. It is important to realise that accuracy of the line of articular cartilage is the chief requirement and that this will only be obtained if the posterior border of the bone is corrected absolutely.

Fixation is necessary. This can be carried out by:

(i) Suture of the aponeurosis and triceps round the fracture line;

(ii) Drilling holes and passing catgut or other absorbable material through them:

(iii) Passing wire through drill holes;

(iv) Drilling the lower fragment to take thick catgut, and fixing it

through the triceps or round a notch cut in the surface of the upper fragment;

(v) Drilling a hole through the olecranon from above, and driving a 2-inch screw through this and down the shaft of the ulna. This has the advantage that it tends to press the olecranon down on to the shaft firmly and there is no doubt about accurate and firm fixation. Hence, this is the method of choice.

The limb is put at rest at a right angle in a plaster trough for six weeks. Movement can be started after five to six weeks.

(b) *The coronoid process* is rarely broken, and then usually as a complication of a posterior dislocation of the elbow joint. Easy reduction or easy re-dislocation is suggestive of the injury. The fragment can rarely be felt.

Treatment consists in reduction of the dislocation, placing the elbow in full flexion and treating the case as a supracondylar fracture.

Prognosis after Elbow Joint Injuries

When there has been a fracture with no displacement, or a perfect reposition after a displacement, in a patient under forty, normal function should be obtained with rest in the correct position and active exercises. Too forcible manipulation, tight bandaging, or the employment of massage may be followed by disastrous complications which are avoidable.

The prognosis is less good when precise reposition is not obtained. *In children, cubitus valgus or varus may result, together with limitation* of movement. These children have good function without full movement. Osteo-arthritis will develop in middle life.

When an open operation is employed, accurate reposition may produce a normal elbow, especially if the operation is performed during the week following the injury. Although osteo-arthritis may never develop, any joint is liable to this condition later in life if it has been opened. In a few cases osteo-arthritis may arise a few years after the operation, even though it has been carried out under ideal conditions and with due care and deftness. When open operation has been performed and the bones not accurately aligned, osteo-arthritis usually occurs early.

Employment of internal fixation near the articular cartilage is followed by a greater limitation of movement and earlier arthritis than when a nail or screw is placed at a greater distance from the joint surface.

Following removal of the head of the radius in an adult, the patient often complains of a weakness of the hand. Extension is usually limited by 20 degrees, but other movements are full. I have seen full range of movement now and again and in some cases limitation of supination.

If it is conceivable that by means of rest and physical treatment an elderly patient with a fracture into the elbow joint will get 90 degrees of flexion and extension and most of the supination range, this should be employed in preference to any operative interference.

ULNA

Shaft. This occurs more commonly in children than in adults, and is due to a fall on the forearm. There is bruising and tenderness at the site of the fracture.

Treatment. (1) *Without displacement.* The hand, forearm, and lower half of the arm should be put into plaster with the forearm

Fig. 2383.—Plaster splint employed in fractures of the shaft of the radius and ulna.

supinated (fig. 2383). Six weeks' immobilisation is required. In the case of fracture in the lower third, a skiagram should be taken at the end of this time as delay in union is common in adults.

(2) *With displacement.* Although displacement is uncommon without fracture of the radius, when present it can be reduced to some extent by traction and manipulation, but there is a tendency to forward tilting of the upper fragment. Immobilisation in plaster is indicated, as in undisplaced fracture.

(3) *Fracture of the shaft of the ulna with dislocation of the head of the radius.* This combined lesion occurs in children usually about the age of six and rarely in adults. It is due to a severe fall on the elbow. There is an oblique fracture of the shaft of the ulna, above the middle

and usually at the junction of the middle and upper thirds. The line of fracture is downwards and forwards, and the upper fragment is flexed so that, in the lateral skiagram, it lies half to three-quarters of an inch in front of the lower fragment. The head of the radius is dislocated forwards ; it can be felt above the capitellum and no longer articulates with the lesser sigmoid fossa of the ulna. This dislocation is frequently not recognised at the time of the injury. It should be regarded as a serious injury.

Treatment. An anæsthetic is given. Traction is employed on the forearm whilst the arm is fixed. The fracture of the ulna is made loose and pressure applied to the front of the upper end of the radius. Reduction of the dislocation should be palpable. If the head stays in place, the elbow is flexed and a skiagram taken to see if the head of the radius is in its correct position. If so, the arm is fixed in this position and the injury is treated on the same lines as a reduced supracondylar fracture.

The reduction and fixation may be simple if carried out within forty-eight hours of the injury. On the other hand, recurrence of the dislocation may occur readily so that the head will not stay in its correct position. If the ulna cannot be pulled out to its normal length, reduction will not be possible. This is sometimes the case shortly after the injury, and invariably so if union of the ulna occurs before reduction of the dislocation, as the radius is proportionately too long for the ulna, and there is also overlap and flexion of the upper fragment.

When reduction of the dislocation is not possible, open operation is advisable. This consists in exposure of the site of the fracture of the ulna. This is freed and made loose, an osteotomy being carried out if necessary. An attempt is then made to reduce the head of the radius without exposing it. If this succeeds, the ulna must be fixed by a plate or peg to ensure that it is straight and of its full length. If the head of the radius is not reducible after exposure of the ulna, an incision is made over it and tight capsular structures are divided before reduction. The ulna is then fixed as described. The elbow should be put up at a right angle in plaster after the operation.

RADIUS

Shaft. Fractures of the shaft with an intact ulna are not common. Greenstick fracture is seen in children. In adults, the middle and lower portions of the radius are those most commonly injured. In fracture *of the middle of the shaft just below the insertion of pronator radii* teres, if there is no displacement, the forearm and lower half of the arm

Following removal of the head of the radius in an adult, the patient often complains of a weakness of the hand. Extension is usually limited by 20 degrees, but other movements are full. I have seen full range of movement now and again and in some cases limitation of supination.

If it is conceivable that by means of rest and physical treatment an elderly patient with a fracture into the elbow joint will get 90 degrees of flexion and extension and most of the supination range, this should be employed in preference to any operative interference.

ULNA

Shaft. This occurs more commonly in children than in adults, and is due to a fall on the forearm. There is bruising and tenderness at the site of the fracture.

Treatment. (1) *Without displacement.* The hand, forearm, and lower half of the arm should be put into plaster with the forearm

Fig. 2383.—Plaster splint employed in fractures of the shaft of the radius and ulna.

supinated (fig. 2383). Six weeks' immobilisation is required. In the case of fracture in the lower third, a skiagram should be taken at the end of this time as delay in union is common in adults.

(2) *With displacement.* Although displacement is uncommon without fracture of the radius, when present it can be reduced to some extent by traction and manipulation, but there is a tendency to forward tilting of the upper fragment. Immobilisation in plaster is indicated, as in undisplaced fracture.

(3) *Fracture of the shaft of the ulna with dislocation of the head of the radius.* This combined lesion occurs in children usually about the age of six and rarely in adults. It is due to a severe fall on the elbow. There is an oblique fracture of the shaft of the ulna, above the middle

and usually at the junction of the middle and upper thirds. The line of fracture is downwards and forwards, and the upper fragment is flexed so that, in the lateral skiagram, it lies half to three-quarters of an inch in front of the lower fragment. The head of the radius is dislocated forwards; it can be felt above the capitellum and no longer articulates with the lesser sigmoid fossa of the ulna. This dislocation is frequently not recognised at the time of the injury. It should be regarded as a serious injury.

Treatment. An anæsthetic is given. Traction is employed on the forearm whilst the arm is fixed. The fracture of the ulna is made loose and pressure applied to the front of the upper end of the radius. Reduction of the dislocation should be palpable. If the head stays in place, the elbow is flexed and a skiagram taken to see if the head of the radius is in its correct position. If so, the arm is fixed in this position and the injury is treated on the same lines as a reduced supracondylar fracture.

The reduction and fixation may be simple if carried out within forty-eight hours of the injury. On the other hand, recurrence of the dislocation may occur readily so that the head will not stay in its correct position. If the ulna cannot be pulled out to its normal length, reduction will not be possible. This is sometimes the case shortly after the injury, and invariably so if union of the ulna occurs before reduction of the dislocation, as the radius is proportionately too long for the ulna, and there is also overlap and flexion of the upper fragment.

When reduction of the dislocation is not possible, open operation is advisable. This consists in exposure of the site of the fracture of the ulna. This is freed and made loose, an osteotomy being carried out if necessary. An attempt is then made to reduce the head of the radius without exposing it. If this succeeds, the ulna must be fixed by a plate or peg to ensure that it is straight and of its full length. If the head of the radius is not reducible after exposure of the ulna, an incision is made over it and tight capsular structures are divided before reduction. The ulna is then fixed as described. The elbow should be put up at a right angle in plaster after the operation.

RADIUS

Shaft. Fractures of the shaft with an intact ulna are not common. Greenstick fracture is seen in children. In adults, the middle and lower portions of the radius are those most commonly injured. In fracture of the middle of the shaft just below the insertion of pronator radii teres, if there is no displacement, the forearm and lower half of the arm

are put in plaster with the forearm supinated. The bone may take eight weeks to join. When there is displacement, it is necessary to correct this to make certain that the full range of pronation and supination is obtained. A manipulation does not always succeed. Under anæsthesia, forcible long-axis traction is employed with the elbow in a position of extension. Fixation in plaster is employed with the elbow bent to a right angle, for fixation in extension leads to swelling of the hand, is uncomfortable, and seldom holds the fragments better than in the position recommended. Failure of this method necessitates open reduction. The fractured area is exposed, and after clearing intervening structures the fragments are brought into normal alignment. If the operation is carried out a few days after the injury, no internal fixation is necessary as a rule. Late open reposition must be followed by internal fixation with a plate or intra-medullary fixation. After the operation, a plaster is employed. Eight or ten weeks may be required for union.

Fracture of the shaft in the region of the pronator quadratus results from the same causes as the Colles' fracture, particularly from a backfire. It is treated in a similar manner. Rarely is reposition impossible, except when there is an injury to the ulna above the head or epiphysis. In these rare cases, an open reposition of both fragments may be required.

Radius and Ulna

Fracture of the shafts of both radius and ulna is a common injury in children and not infrequent in young adults from heavy falls on the forearm, and in machinery and motor accidents.

Greenstick fracture. (*a*) *Without displacement.* A plaster splint is applied from the middle of the arm, and over the forearm to the palm of the hand, with a turn round the cleft between the thumb and first finger (see fig. 2383). It is left on for four weeks in children under six and for six weeks after that age. (*b*) *With angulation.* An anæsthetic is given, and the bones are cracked through and then placed straight. A plaster is applied as above. During the setting of the plaster a groove is moulded in the long axis of the limb between the two bones. If the bones are not cracked through, the angulation will tend to recur.

Transverse or oblique fracture with no displacement is treated in plaster as described. When there is displacement, there is usually pronation of the lower radial fragment, in addition to overlap of one or both bones. An anæsthetic is given, and strong long-axis traction is employed with the forearm supinated, assisted by digital manipulation. This succeeds more often in patients of adolescent age than in adults.

If the bones appear to have hitched, a plaster is applied as for the other forearm fractures. Lateral and antero-posterior X-ray pictures are taken to see if the position is satisfactory.

The setting of these fractures is often very difficult. If the traction has obviously not hitched the bones, an attempt can be made by bending the forearm at the site of the fracture and then attempting to lift the lower fragments on to the upper ends of the bone. This may be dangerous, and is only likely to be successful within forty-eight hours of the injury. Failure by manipulation necessitates open operation. When the line of fracture is transverse or approximately so, reposition without fixation will suffice, as an interlock will generally occur, sufficient to be held by plaster fixation.

When the fracture line is oblique, internal fixation is necessary in the radius, such as a plate or intra-medullary fixation, but it is unnecessary to fix the ulna even if it has to be exposed. In the case of fracture of the upper third of the radius, internal fixation is usually advisable.

In all fractures of the shafts of the radius and ulna, except greenstick fractures, a skiagram should be taken when the plaster is removed. A number are not united in six weeks, and re-fracture following a trivial injury is prone to occur, particularly in children about ten years old.

The fingers can be moved freely with the plaster *in situ*. Elbow movements quickly return when the plaster is removed, and pronation and supination are freed by exercise and use.

Cross union will not occur if the bones are properly aligned and the forearm placed in supination. The grooving of the plaster during its setting is an additional prevention of this.

FRACTURES ABOUT THE LOWER END OF THE RADIUS

COLLES' FRACTURE

This is a fracture of the lower end of the radius, ½-inch above the wrist joint. The anterior surface of the radius is broken at a lower level than the posterior surface. The fracture is most commonly seen in women over forty years of age, and is frequently comminuted in elderly persons.

Additional fractures are often associated: (1) Ulnar styloid process, torn off by pull of internal lateral ligament. The process seldom unites by bony union; (2) T-shaped or Y-shaped crack running into the wrist joint.

Deformity. This is due almost entirely to the causative violence,

which is invariably applied to the thenar eminence by a fall on the outstretched hand. As a result, the lower small fragment is driven backwards and impacted on the radial or external side.

Diagnosis. Special attention should be directed to the site of local tenderness over the lower end of the radius, to pain on gripping, and to the relation of the ulnar and radial styloid processes to one another. When there is displacement the classical "dinner-fork" deformity is obvious. Many "sprained" wrists are in reality Colles' fractures with impaction and no displacement.

X-ray examination. In viewing the films of a Colles' fracture certain points should be taken into consideration, with a view to prognosis and treatment:

(1) *Antero-posterior view:* (*a*) The degree of radial tilting and radial impaction; (*b*) The presence of fracture of the ulnar styloid process; (*c*) Whether the fracture line runs into the radio-ulnar joint, or is above it; and (*d*) Whether the fracture is comminuted and involves the wrist joint.

(2) *Lateral view:* (*a*) Backward displacement of the lower fragment; (*b*) Backward *tilt* of the lower fragment. As a result the joint surface ceases to be at right angles with the shaft of the bone. The backward tilt is of special importance for, if not corrected, instability of the wrist joint and weakness of grip will result.

Treatment. Except in extreme senility, every recent case of Colles' fracture should be treated actively and an attempt made to reduce deformity and fix the fragments.

Aims. Although perfect anatomical alignment is desirable and usually obtainable, certain cases of severe comminution prevent this perfection. It is essential to correct *backward tilt* and radial deviation. If some degree of backward displacement of the lower fragment persists, a reasonable functional result will follow, provided the tilt has been corrected.

Technique of Reduction. Colles' fracture may be corrected with deliberation and care under nitrous-oxide anæsthesia. This probably forms the ideal anæsthetic for the fracture, as it gives a sufficiently long period of relaxation, is a much more rapid method than local anæsthesia, and avoids the risk of sepsis. Local anæsthesia gives good results when used in organised fracture clinics, but for general casualty work N_2O has obvious advantages.

The fracture is disimpacted by increasing the deformity in the following manner: The surgeon stands facing the patient and grasps the injured wrist between his thenar eminences. The fingers of the

"palmar" hand grip the ulnar border of the patient's hand. Pressure by the "palmar" hand increases the deformity and a slight wriggle will complete the disimpaction. The position of the surgeon's hands is now reversed. The "dorsal" hand presses on the lower fragment, while counter-pressure is made by the "palmar" hand on the lower third of the forearm. The lower fragment is thus carried palmarwards

Fig. 2384.—COLLES' FRACTURE (COMMINUTED)

The upper films show: (1) Backward and upward displacement and tilting; (2) comminution of the fragment, so that the radial styloid is separated from the other piece of the lower fragment. The lower films show the same fracture immediately after setting.

and into ulnar deviation. In difficult cases the lower fragment may be pushed forwards over a wedge. Usually, however, the reduction is comparatively easy and can be carried out in three distinct steps: (1) Increase of deformity followed by disimpaction; (2) Correction of backward displacement and backward tilt; and (3) Ulnar deviation.

Failure to obtain complete disimpaction is a frequent cause of faulty setting.

In "late" cases, an attempt should be made to correct deformity up to 10 days. After this time, correction by open operation may be necessary.

Fixation.

(1) *By Carr's splint.* The splint is padded with felt. A thick felt pad is attached to the splint by strapping, so that it lies beneath the wrist joint. It should be $\frac{3}{4}$-inch thick, its function being to produce slight palmar-flexion of the wrist. The bar of the splint should be well "home" in the web of the thumb, and the hand well deviated to the ulnar side. The splint is fixed by two strips of $1\frac{1}{2}$-inch strapping, one applied in the upper third of the forearm, and the other across the dorsal aspect of the wrist joint *below* the fracture. It is well to pass the strapping over small felt pads, or blistering of the skin may be caused. Finally, a firm calico bandage is applied. This should commence from

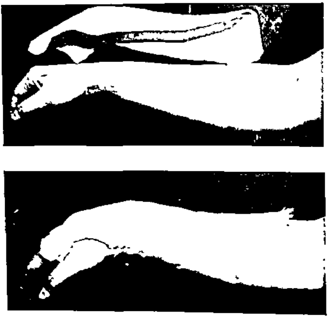

Fig. 2385.—Showing dorsal plaster-cast for Colles' fracture and method of fixation by flannel bandage.

without inwards across the dorsum of the forearm; when the wrist is reached, a loop of bandage is taken round the bar of the splint and returned across the dorsum in the opposite direction. The bandage is then finished off in the usual manner. The loop serves to maintain the hand in ulnar deviation.

(2) *Fixation by plaster.* Instead of Carr's splint, fixation may be made by an unpadded dorsal plaster slab. The slab should cover the whole of the dorsal aspect of the forearm and extend to the knuckles (fig. 2385). The wrist is held in ulnar deviation and slight palmar-flexion while the cast is hardening. A turn of plaster bandage or a loop of wire should pass across the palm. It should be narrow so that free movement of the fingers and thumb can take place. The slab is retained by a covering of flannel bandage, over which is applied one layer of wet plaster bandage.

After-Treatment.

General. The patient is told to move the shoulder, fingers and thumb from the first, and should be encouraged to make as much use of them as possible to grasp light objects or in attempts to play the piano. This will be much easier when the plaster-cast is used.

An arm sling may be necessary to make the patient comfortable for a few days, but it should be discarded as early as possible. Neglect of this leads to inadequate finger movements and to stiffness of the shoulder joint, which is a common and unrecognised complication of Colles' fracture.

Special. (1) If a Carr splint is used, it should remain undisturbed for ten days. Massage is then started. The bandage and strapping are removed, but the limb remains on the splint. Gentle massage and assisted finger movements are employed. Attention should also be given to the elbow and shoulder.

At the end of three weeks the splint may usually be discarded; if all local tenderness has disappeared, movements of the wrist joint may then be commenced.

(2) The plaster-cast should remain undisturbed for four or five weeks. Active use of the limb is encouraged, and when confidence is gained more household duties can be performed.

Subsequent treatment consists in the wearing of a firm wrist bandage, and in physio-therapy if free movement does not return quickly.

Common Mistakes.

(1) Fracture not completely reduced before splint is applied (fig. 2386); (2) Neglect to make an X-ray examination after reduction;

Fig 2386.—Skiagram of Colles' fracture. Imperfect reduction. Note backward tilt of the lower fragment.

Fig 2387.—Malunion in Colles' fracture, with impaction and severe backward tilt of lower fragment.

(3) Removal of splint too early, when callus is still soft; (4) Violent massage and movements which cause deformity to recur; and (5) Badly-applied splint or plaster resulting in: (*a*) Blistering of the skin and œdema; and (*b*) Limitation of finger and thumb movements.

Common Complications.

(1) Malunion (see fig. 2387).

(2) Tenosynovitis of extensor tendons.

(3) Arthritis of wrist and radio-ulnar joints.

(4) Stiff elbow and shoulder.

A rare complication is *rupture* of the *extensor pollicis longus tendon*, which may occur at any time between a week and many years after the injury. (See also Vol. II, page 3457.)

The rupture is more frequently found when early active movements of the thumb have been instituted, which lends support to the view that the tendon is traumatised against a sharp bony spicule.

BACKFIRE FRACTURE

The cause is a backfire while swinging the engine of a motor vehicle, hence the fracture is seen almost exclusively in young male adults.

It may happen in two ways:

(1) The starting-handle is grasped between the fingers and thumb. The sudden jerk is transferred to the region of the lower end of the radius.

Three types of fracture may result:

(*a*) Colles' fracture

(*b*) Oblique fracture into the wrist joint from the base of the styloid process.

(*c*) Fracture of radius 1 to 3 inches above the wrist joint.

(2) The starting-handle is grasped with the fingers only. The jerk forces the handle out of the grasp of the fingers and the handle flies round, striking the dorsal aspect of the forearm in the lower third. The site of fracture will be at this level.

SMITH'S FRACTURE

A reversed Colles' fracture. The displacement of the lower fragment is forwards instead of backwards.

SEPARATED LOWER RADIAL EPIPHYSIS

A common injury among adolescent males. The cause is a fall on to the outstretched hand, and the condition corresponds with a Colles' fracture in later life. It is sometimes bilateral.

The lesion is a fracture-dislocation of the epiphysis, the fracture

consisting of a small triangular fragment broken from the dorsal aspect of the radius and remaining attached to the epiphysis.

Deformity is similar to that of a Colles' fracture (fig. 2388).

Treatment. The small fragment of radial shaft makes the reduction of the separated epiphysis difficult.

Should manipulation fail, forcible correction over a wedge will nearly always succeed, provided this is attempted early. Fixation is by a plaster-cast. If any backward tilt persists after attempted reduction, the wrist should be put into full palmar-flexion and ulnar deviation.

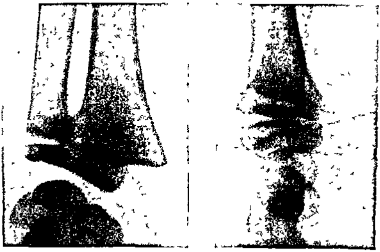

Fig 2388.—SKIAGRAMS SHOWING SEPARATED EPIPHYSIS OF LOWER END OF RADIUS WITH FLAKE TORN OFF LOWER END OF DIAPHYSIS. LATERAL VIEWS SHOWING DISPLACEMENT AND REPOSITION AFTER MANIPULATION

Open operation is inadvisable because of the danger of damaging the epiphysial line and thus interfering with bone growth, but in old-standing unreduced cases an osteotomy may be required.

CARPAL BONES

SCAPHOID

This is a common injury which is frequently misdiagnosed as a "sprain" of the wrist (see fig. 2389). Every "sprain" should be subjected to X-ray examination. The bone fractures in its narrow central portion, and the use of a lens may be necessary to see the fracture line in the skiagram. Some weeks after the injury the fracture line becomes wide and obvious owing to separation of the fragments, absorption of bone, and decalcification. Fixation must be maintained for a long time, as otherwise the newly-formed blood-vessels will be torn across by movement and non-union will result.

Diagnosis. History of a fall on the hand or of a sudden jerk, pain, swelling, and tenderness on pressure in the "anatomical snuff-box" and over the tuberosity of the scaphoid, at the base of the thenar eminence; there is, in addition, limited dorsiflexion of the wrist.

Treatment.

(1) *Recent cases.* The wrist is fixed in full dorsiflexion by means of a plaster-cast. The cast should be removed at the end of six weeks and X-ray pictures then taken. If bony union is not complete, the cast is reapplied for a further four weeks.

(2) *Late cases.* If the injury has remained untreated for some weeks, the scaphoid will appear decalcified. This irregular decalcification is referred to as "cavitation." One of the fragments may appear denser than the other, as a result of diminished blood supply.

A plaster-cast is applied as before, but a much longer period of

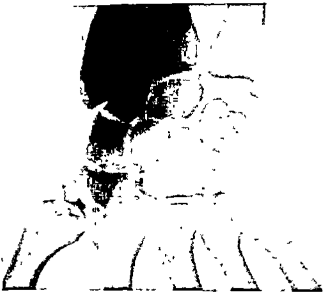

Fig. 2389.—Skiagram showing fracture of the scaphoid.

immobilisation will be required—as long as eight months may be necessary. Active use of the arm, fingers and thumb must be encouraged during the period of immobility.

(3) In *very late untreated cases*, the fracture surfaces may appear sclerosed, as in other bones in which non-union is present. It is useless to expect this type to unite by immobilisation, unless the fragments are first drilled by Beck's method to provide channels through which blood-vessels may grow.

(4) The *operation of removal* of the scaphoid or of a fragment is sometimes advocated. The result of this procedure is poor, arthritis and weak grip being frequent sequelæ.

SEMILUNAR BONE

Dislocation of the semilunar bone is found occasionally, as a result of falls and blows upon the outstretched hand. The mechanism by

which the dislocation is produced may be described in three stages:

(1) Dorsal dislocation of the hand, upon the semilunar and radius.
(2) Upward displacement of the hand, so that the head of the os magnum lies behind the semilunar. The weak posterior ligament between the radius and semilunar gives way and the bone starts to rotate forward as it is pressed upon by the os magnum.

Fig. 2390.—Skiagram showing dislocation of the semilunar bone. Note that the bone has been pushed forwards and rotated by the os magnum.

(3) The semilunar rotates through 90 degrees, so that its concave surface looks forward and the head of the os magnum articulates with the radius. On occasions, the semilunar may rotate further on the anterior ligament, so that it rests on the anterior surface of the lower end of the radius, the concavity of the bone facing the elbow.

Diagnosis. History of injury, limited movement in the wrist (especially flexion), and effusion. In recent cases the bone may be felt on the front of the wrist as an indistinct swelling. Tingling in the distribution of the median nerve may be present.

X-ray examination. The lateral view is the more important, and shows the bone lying in front of the os magnum, with its crescentic margin looking forward (fig. 2390).

Complications.

(1) The scaphoid may be fractured in addition. If this is so, the inner fragment will be found dislocated forward with the semilunar.

(2) One of the "horns" of the semilunar may be fractured, usually the posterior.

(3) The injury is liable to be misdiagnosed in the absence of X-ray pictures. Old-standing dislocations are difficult to reduce and may necessitate open operation.

Treatment.

(1) *Recent cases.* Reduction is effected by manual traction, under anæsthesia, on the fingers and thumb. Counter-traction is made on the forearm by an assistant, or the method of fixing the flexed elbow to a wall hook by means of a webbing sling, as advocated by Böhler, may be used. The traction is kept up steadily for at least ten minutes, but this alone does not reduce the dislocation; pressure upon the dorsal aspect of the wrist will cause the os magnum to snap back into place, provided the dislocation is in Stage (1).

A skiagram is taken, confirming that reduction is complete. If the method fails, a second attempt should be made. In any case, the widening of the gap between radius and os magnum will render the subsequent operation easy.

(2) *Open operation* is only indicated where traction has failed. The interval between radius and os magnum is exposed by a straight incision on the dorsal aspect, on the side of the radial tubercle. The tendons are retracted and the head of the os magnum levered back into position. Approach from the front of the wrist is referred to later.

Fixation. This is by dorsal plaster slab for three weeks. If the scaphoid is fractured, fixation must be for eight weeks. X-ray examination at the end of this period should confirm bony union, otherwise the period of fixation must be extended. Subsequent massage is unnecessary.

Removal of the semilunar leads to a weak wrist and grip and should be avoided.

Note. Kienboch's disease is an affection of the semilunar bone causing necrosis of unknown pathology. It is not related to dislocations, but may result from compression fracture on this bone.

OTHER CARPAL BONES

These are treated by the application of a plaster-cast, with the wrist in dorsiflexion. Fixation for three to six weeks is required. Active use of the arm and fingers should be encouraged.

METACARPALS

Bennett's fracture. The so-called boxer's fracture is a fracture-dislocation of the base of the first metacarpal. The shaft is displaced in

a radio-dorsal direction, while a small triangular fragment remains in its normal relation to the trapezium on the ulnar palmar side. As the joint between the metacarpal and trapezium is of special importance in movements of the thumb, accurate reduction is essential. A comparable injury occurs before the epiphysis at the base of the first metacarpal has fused. The proximal fragment consists of the epiphysis and a wedge-shaped piece of bone.

Treatment. The patient is anæsthetised. The surgeon grasps the wrist with one hand and exerts powerful traction upon the thumb with the other. The prominent base of the metacarpal is then pushed back into position and the thumb fully abducted.

Fixation. A complete plaster-cast is applied to the forearm and extends to the knuckles. It continues as a "sleeve" to the tip of the thumb. It is advisable to place a small piece of felt over the base of the metacarpal. While the plaster is setting, the thumb is held in full abduction, and the plaster is moulded firmly over the site of fracture, which is protected from undue pressure by the felt.

The cast should be kept in position for three weeks. Should manipulative reduction fail, resort must be had to skeletal traction, as described subsequently.

Fractures of 2nd to 5th Metacarpals.

The fracture may be of the base, neck, or shaft. The former are commonly transverse, while the latter is an oblique fracture. Fracture of the neck of the 5th metacarpal bone is common. The shafts of several metacarpal bones are not infrequently fractured by the same injury. Deformity, if present, consists of overlap, with antero-posterior or lateral displacement.

Diagnosis. Local tenderness, inequality of the knuckles when the hand is clenched, and pain on finger movement. A useful sign is elicited by pulling on the fingers, or by pressure on the knuckles. If these cause pain, a fracture is almost certainly present. Skiagrams, of course, are essential.

Treatment.

(1) *Fracture without displacement.* Fixation by a padded malleable iron splint, applied on the dorsal or palmar aspect of the metacarpal and corresponding finger, is all that is necessary. Four weeks will be required for union.

(2) *Fractures with displacement.* Continuous traction must be applied until the fracture is united.

Method. An anæsthetic is given. The forearm is encased in a well-fitting plaster-cast, extending from below the elbow to the knuckles.

While the plaster is setting, an assistant makes traction on the fingers and the displacement is corrected as much as possible by manipulation. That portion of plaster over the site of fracture is well moulded. A piece of malleable iron or stout iron wire is fastened to the plaster-cast by a few turns of plaster bandage in such a way that it projects beyond the finger. The end of the wire is bent into a hook. The traction apparatus on the finger is now connected to the wire hook by a piece of tape or elastic. The line of traction should cause the finger to be semi-flexed. Continuous traction may be kept up in this way for an indefinite period. Daily inspection is necessary to maintain the correct degree of traction. Four weeks' traction will usually suffice. This method is particularly valuable in the treatment of open fractures. Extension is made from the corresponding finger in one of the following ways:

(*a*) *By adhesive strapping.* A piece of 1-inch strapping, twice the length of the finger, is folded at the centre over a piece of string. The

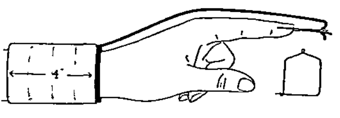

Fig. 2391.—Apparatus for treating fractures of the metacarpus or phalanges. Plaster-cast round wrist incorporates malleable wire extending beyond a finger. A wire clip (inset) has been inserted through the pulp of the finger and an extension tape is attached to this and to the wire.

two "limbs" thus made are attached to the lateral aspects of the finger and bound firmly by ¼-inch oblique strips. Considerable traction may be exerted in this way.

(*b*) By a spring wire clip, inserted into the pulp of the finger (fig. 2391).

(*c*) By transfixion of the nail and terminal phalanx with a short length of Kirschner wire. The wire is then bent into a loop and twisted together.

DISLOCATION OF THE PHALANGES

Simple traction is sufficient to overcome the majority of these dislocations.

Dislocation of the metacarpo-phalangeal joint of the thumb may be difficult to reduce, owing to the interlocking of the flexor tendons or joint capsule with the head of the metacarpal. Should manipulation fail, an incision is made over the flexor aspect and the tendons drawn aside. Reduction is then easy.

FRACTURES OF THE PHALANGES

Proximal. The proximal fragment becomes flexed and the distal fragment hyperextended by the action of the lumbricales and interossei muscles.

Treatment. The deformity can often be corrected by manipulation, and the finger immobilised in a position of flexion on a malleable iron splint applied to the palmar aspect. Failing this, one of the methods of traction advised for fractures of the metacarpal bones should be employed. The malleable iron splint should be incorporated in the plaster-cast or malleable wire be placed on the dorsum, and continuous traction made while the finger rests upon it (see fig. 2391). Four weeks will suffice. Active exercise of the sound fingers must commence at once.

Fractures of the middle and terminal phalanges. Displacement should be reduced and the finger immobilised on a malleable iron splint for three weeks.

Transverse fracture of the terminal phalanx often remains untreated, and fibrous union or non-union may result, with no disability.

Fractures with joint involvement. These occur as a result of blows upon the tip of the extended finger. Treatment is on general lines. Dislocations are reduced by manipulation, but occasionally open operation is required owing to displaced bone fragments. Limited movement frequently follows fractures into an interphalangeal joint.

Avulsion of a bone fragment at the insertion of the extensor tendon is sometimes seen. The result is a "mallet finger." Treatment is by fixation on a malleable iron splint or by plaster for six weeks. When fixed, the finger should be flexed at the middle joint and extended at the terminal joint. This position brings about relaxation of the extensor tendon (see also Vol. II, page 3448).

Multiple fractures of metacarpal bones and phalanges are best treated by extension on all the fingers. A plaster-cast is applied round the forearm. A hoop of wire with two 6-inch arms is made. The hoop extends round the ends of the fingers and 2 inches beyond. The arms are fixed in the plaster-cast. The extensions are attached to the hoop. The extensions can be by strapping, or by pin extension inserted through the terminal phalanges or through the pulp of the fingers.

RIBS

Fractures result from direct violence or compression. It is common to see one or two ribs broken in the middle, or a large number just in front of the angles, when there are other severe injuries. In the

elderly, fracture of one or two ribs is relatively common, whereas in children it is rare. except in severe road accidents in association with other injuries.

Signs and Symptoms. There is severe pain over the fracture which is increased by deep breathing and coughing. Crepitus may be felt and local tenderness. Displacement is seldom present. Pain is produced at the site of the fracture by compression of the chest wall.

Complications result from injury to thoracic viscera, particularly to the pleura and lungs in the upper ribs, and to the liver and kidneys below. The signs of surgical emphysema will be evident, and those of visceral injury are usually more prominent than those of fracture. Compound fractures are readily diagnosed by inspection of the wound, and often extend to the pleura.

Treatment. When no complication exists and the patient is fit, confinement to bed is not necessary. After forced expiration, the chest is strapped for two-thirds of its circumference, so that two ribs above and below the injured ones are covered. This should be retained for three weeks.

Prognosis. No permanent injury results from an uncomplicated case. Pain is often very persistent, particularly in a heavily-built man. Ordinary light occupation can be followed soon after the injury in most cases, but a man employed on heavy labour should be kept off work for three months. Prolonged fixation appears to assist this type of case.

Pneumonia may follow in the aged, and this complication at any age is likely to be more serious than the fracture itself.

STERNUM

Fracture is rare and is due to a severe crush. Sometimes it occurs at the same time as a flexion-fracture of the dorsal spine. There is usually hæmorrhage into the anterior mediastinum. Examination shows a bruise and tenderness over the site of the injury. Displacement is palpable, particularly when the manubrium is displaced backwards in relation to the body of the sternum. Thoracic viscera may be injured. Treatment consists in putting the patient to bed for a month with a back-rest. Local treatment is not necessary. No manual work should be allowed for two months.

SPINE

The majority of these fractures are caused by *indirect violence*, such as falling from a height on to the buttocks, or by a heavy weight

falling on to the back while the patient is stooping. Fractures produced in this manner are almost always of the compression type. *Direct violence* and muscular actions also play a part, the former being responsible for fractures of spinous processes, transverse processes, and the rare condition of fracture of a lamina. It has been pointed out (S. T. Irwin, *B.M.J.*, Jan. 4th, 1936) that fracture of the transverse processes, so common in the lumbar region, is probably caused by the pull of the quadratus lumborum muscle rather than by direct violence.

A convenient *classification* of spinal fractures is the following:

(*a*) Compression fractures of a vertebral body, 40 per cent.
(*b*) Fracture of spinous process, transverse process or lamina.
(*c*) Fracture-dislocation in the cervical region.
(*d*) Fractures of special vertebræ (atlas and axis).
(*e*) Fracture of the coccyx.

Site. Compression fractures occur most frequently in the dorsi-lumbar region of the column (10th dorsal to 2nd lumbar). Fracture of transverse processes in the lumbar region, and fracture-dislocation in the cervical (commonly 5–6th cervical). Fractures in the upper dorsal region are rare, owing to the support given by the ribs.

Diagnosis. This is usually straightforward if it is remembered that every suspected case of spinal injury must be examined by X-rays, both in the antero-posterior and lateral planes. Occasionally a stereoscopic view may be of service in the cervical region. Considerable deformity may occur, but spontaneous reduction may take place whilst the patient is being transported to hospital, and unless the skiagrams are carefully examined the fracture may be missed. Such cases probably explain the slow collapse which may be discovered in a vertebral body some months after what appeared to be a trivial injury. This condition has been described under the name of *Kümmel's disease* (spondylitis traumatica).

(*A*) *Compression Fractures*

This type is the result of acute flexion of the spinal column. The mid-dorsal region is occasionally involved. Only 30 per cent of cases are complicated by severe cord or nerve injury. The natural tendency of this part of the column is to flex when under stress, and one vertebral body becomes "nipped" between the bodies of the vertebræ above and below (see fig. 2392). Owing to the spongy structure of a vertebral body the thin cortex of bone is easily broken through and the anterior portion of the bone is pushed forward, thus putting the anterior common ligament under tension. Damage to the intervening intervertebral

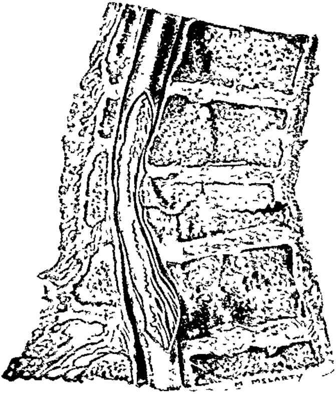

Fig. 2392.—Compression fracture of vertebral body. Note the wedging and increase of antero-posterior diameter.

(*Museum, King's College Hospital.*)

Fig. 2393.—Skiagram showing compression fracture of vertebral body caused by acute flexion.

discs may also occur and has been well described by Schmorl and Beadle (fig. 2393).

In cases where the spinal cord is injured, there may be compression followed by œdema, hæmorrhage into the cord, or complete transection (fig. 2392). Paraplegia will result in each case, but it is impossible to tell in the early stages how much recovery will take place.

Prognosis. This will depend upon: (*a*) Early diagnosis; (*b*) signs of cord injury; and (*c*) the efficiency of the treatment.

In the absence of cord injury, the prognosis is excellent provided that disimpaction and immobilisation for a sufficiently long period are carried out. Should the deformity remain unreduced, persistent pain and disability are to be expected.

Treatment. The deformity is reduced by the method advocated by Robert Jones and developed by Watson Jones (*Journ. Bone and Joint Surg.*, 1934, XVI, 30–45).

The principle is simple in that it consists of hyperextension of the spine. This is brought about by the patient's own weight and no extra force is required. The apparatus consists of two tables, one rather higher than the other. The patient lies prone, with his arms and shoulders resting upon the higher table and his legs upon the lower. The portion of his body between the clavicles and the groins is suspended in mid-air and "sags" down, thus producing sufficient hyperextension to complete reduction of the fracture. A preliminary injection of morphia ¼ gr. is given, but no anæsthetic is required and only slight pain and discomfort are experienced. It is convenient to provide a canvas sling round the upper part of the chest which is connected to a pulley on the wall behind, and thus relieves the arms of a considerable portion of the body weight.

In this position a *lightly*-padded plaster jacket is applied over a vest or bathing suit. A small felt pad should be placed in the lumbar region and the plaster well moulded round the pelvis. The jacket extends from the clavicles to the groins (see fig. 2394). A window is cut over the lumbar felt pad, but the felt is not disturbed.

The patient is returned to bed, but may sit up immediately and is allowed to walk in a week.

After-Treatment consists in encouraging a normal mode of life and in graduated exercises to the limbs, pelvis, and abdominal and spinal muscles. The jacket should be worn for a period of from three months in mild cases to six months for a severe comminuted fracture. The condition of consolidation of the fracture must be checked by skiagrams taken through the plaster before removal of the

jacket. Following upon removal of the jacket the patient continues his exercises and commences flexion of the spine.

Reduction of Special Spinal Fractures.

(1) *Dorsal region.* The spine is fixed just below the site of fracture by means of a sling tied to the table legs. Hyperextension by the shoulder sling then exerts great force at the site where it is required.

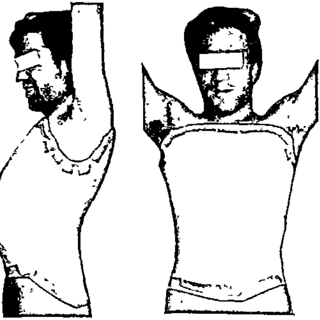

Fig. 2394.—PLASTER JACKET APPLIED FOR FRACTURE OF THE LOWER DORSAL SPINE.

Note. (*a*) A rare type of comminuted fracture is caused by hyperextension. It can be recognised in a lateral skiagram by the fact that the posterior part of the vertebral body remains intact while the anterior half separates into an upper and lower fragment In this type of fracture hyperextension is obviously contraindicated

(*b*) Some authors advocate that fractures occurring in the portion of the column where the convexity is backward (i.e. the upper-dorsal region) should be treated by reduction followed by recumbency in a plaster bed, owing to the tendency for the deformity to recur.

(2) *Cervical region.* The patient lies supine, with his head and shoulders projecting beyond the table. Hyperextension is effected by allowing the head to drop back. The plaster-cast is made to include the head, neck and upper trunk.

(3) *Late cases of crush fracture, with persistent pain.* In these cases, the question of fixation of the damaged vertebræ by a short Albee bone graft should be considered.

(4) *Fractures complicated by paraplegia* (fig. 2395). Immediate relief of pressure by hyperextension is indicated. Laminectomy is useless in the majority of cases, whether performed early or late.

The prognosis in fractures in the lower dorsal and lumbar regions is good, that in the upper dorsal region is poor.

First-Aid treatment (*when diagnosed by a doctor*). Arising out of these methods of treatment, it is obvious that when a patient is transported from the scene of accident he should lie in the *prone position.*

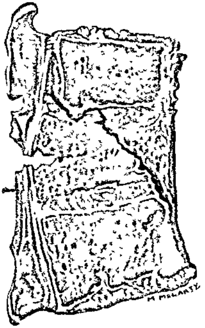

Fig. 2395.—OBLIQUE FRACTURE-DISLOCATION INVOLVING TWO VERTEBRÆ AND THE INTER-VERTEBRAL DISC. THE SPINAL CORD HAS BEEN DAMAGED (*Museum, King's College Hospital.*)

In many instances, carried in this way, the fracture is found to be reduced on arrival at hospital, although the presence of paraplegia may indicate that a serious deformity was at one time present.

(*B*) *Fractures of Spinous and Transverse Processes and of the Laminæ*

(1) *Spinous processes.* There are fractures by direct violence, muscular action, or hyperextension. The superficial processes of the lower cervical and upper dorsal region are prone to injury. Immobilisation for a few days, followed by physical treatment, is all that is necessary.

(2) *Transverse processes.* Those of the lumbar vertebræ are most often affected. Traction by the quadratus lumborum is often responsible, but direct violence accounts for a number of cases. Care should be taken not to mistake an un-united epiphysis for a fracture. This may be of medico-legal importance. As the majority of cases occur in labouring men, the period of disability is longer than might be expected and some pain may persist for as long as three months.

Treatment. It is advisable for the patient to rest in bed for fourteen days. The injured part may be firmly strapped over a piece of felt. Subsequently, physical treatment should be employed. The fragment should never be removed.

(3) *Lamina.* Pressure on the spinal cord may be present through bone being driven inwards by direct violence, or the fracture may be confined to a fissure. If any displacement is present, or if the cord is pressed upon, treatment should be by open operation, in order to remove depressed portions of bone or blood clot.

(C) *Fracture-Dislocations in the Cervical Region*

(1) *Above the 4th Segment.*

(*a*) *Simple dislocations* are usual, although an articular facet may be fractured. The cord is uninjured. If one articulation is dislocated, there will be rotation of the upper vertebræ upon the lower. If both

Fig 2396.—Skiagram showing fracture of the body of the fourth cervical vertebra with forward tilting of the vertebra above.

are dislocated. the upper vertebræ will be displaced forwards. Pain, stiffness of the neck. and accurate skiagrams will make the diagnosis clear (fig. 2396). The nerve-roots may be injured.

Treatment is by immediate manipulative reduction, if necessary under an anæsthetic. The manœuvres consist of extension, side flexion, and rotation, and reduction is often effected with a click. The neck is immobilised in a plaster collar for six weeks.

(*b*) *Fracture-dislocation* in this region results in sudden death from respiratory failure due to severe cord injury.

(2) *Below the 4th Segment—Cord Injured.*

Sudden death may occur, or if the phrenic nerves escape the patient may live. The prognosis is poor and the complications of

bed-sores, retention of urine and ascending pyelonephritis are inevitable.

(a) *Injury at level of 5th segment:* Complete paralysis of arms.

(b) *Injury at level of 5th and 6th segment:* Arms held in abduction, with elbows flexed and forearms supinated—" Kamerad " position.

(c) *Injury below 6th segment:* Partial paralysis of hand. The arms can be moved.

The level of the fracture may be localised by neurological examination (see page 5515).

Treatment. Should evidence of cord injury be present, without bony displacement, the spine is fixed by a plaster-cast, including the head, but no other treatment is instituted (Cotton).

If displacement is present, reduction should be attempted by manipulation, and the spine subsequently immobilised.

The *prognosis* in such cases is usually hopeless, the patient dying months or years later.

Cord Uninjured.

Reduction is effected by manipulation, or, should this fail, by gradual extension. This is applied by a leather " halter " which grasps the chin and occiput and to which a weight extension may be attached. Subsequently, immobilisation in a plaster collar for three months is advisable. The collar rests on the shoulder, to which it should be moulded, and fits accurately round the chin, lower jaw and occiput. For more secure fixation the plaster may be extended posteriorly to a band encircling the head.

(D) *Fractures of Special Vertebræ*

(1) *Atlas.* The force applied to the vertex of the skull tends to drive the occipital condyles into the condyles of the atlas. These face inwards and so the bone tends to be " spread " laterally. The posterior arch, being the weaker, is broken. Forty-five per cent of cases are non-fatal. The odontoid process of the axis may be fractured in cases where hyperextension of the neck has occurred.

Diagnosis depends upon the history, and upon inability to nod or to rotate or support the head without pain. Anæsthesia or neuralgia may be found in the distribution of the great occipital nerve. *Examination should include inspection of the spinous process for undue* prominence, and of the pharynx for projection of the lateral mass.

Treatment. In the presence of deformity, manipulation or extension may be attempted. Sudden death may result from displacement of the odontoid process against the cord; should this be fractured, careful X-ray examination must be made before attempting any

manipulation. Immobilisation, as for high cervical fractures, is advised.

(2) *Axis.* The common site is the base of the odontoid process. It is caused by acute hyperextension of the neck, or by pressure upon the head when the spine is held rigid. Union by bone is rare.

Treatment follows the general principles already outlined.

(*E*) *Fracture of the Coccyx*

A common accident, due to falls while descending the stairs, the coccyx being struck against a projection. (Coccygeal neuralgia is common among women after falls on the buttocks, but is not necessarily associated with a fracture.)

Diagnosis. Rectal examination should always be made; the coccyx can be grasped between the finger and thumb, and pain on movement, or deformity, be observed. Forward displacement may interfere with child-birth.

Treatment. This consists of: Reduction of any deformity by a finger in the rectum; rest in bed for fourteen days; and excision of the fragment or of the whole coccyx may sometimes be necessary.

PELVIS

There may be fractures of the true or false pelvis (i.e. above or below the pelvic brim), or of the sacrum, coccyx or acetabulum. The

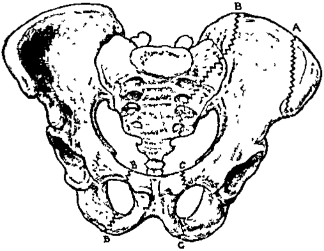

Fig 2397.—Illustrating types of fracture of the pelvis
A. Fracture of iliac crest
B B B. Oblique fracture.
C C. Fracture confined to pubis and ischium

cause is usually violence applied directly, either as a result of road accidents, falls from a height, or crush injuries. According to statistics (published in 1929) of 100 cases, 44 per cent involved the whole pelvic girdle, 24 per cent the pubis, and 18 per cent the ilium.

Types.

(1) *Fractures of the ilium* consist of linear or stellate cracks, causing separation of a portion of the iliac crest (fig. 2397, A). Crepitus is obtainable, and a large hæmatoma may be present in the iliac fossa. Visceral complications are rare.

Avulsion of the anterior superior or inferior iliac spine may occur as a result of muscular traction.

(2) *Fractures of the pubis ;* both rami were accompanied by visceral complications in about 20 per cent of cases.

(3) *Fractures of the whole pelvic girdle.* Two types are common :

(*a*) An oblique fracture running through the ilium and sacral foramina on one side, with a fracture of the pubis and ischium on the opposite side (see fig. 2397, B–B–B).

(*b*) The fractures of ilium, sacrum and pubis may be limited to one side only.

Complications. Either type may be associated with injury to viscera, and, in the series quoted, rather more than 10 per cent sustained this complication. In every case in which injury to viscera occurred, of whatever type, the accident was due to being run over in the street.

(*a*) *The membranous urethra may be torn.* Signs of this should be sought in every case in which the pubic bones are involved. Pain, retention of urine, and perineal hæmatoma are typical symptoms. Blood may be "milked" from the urethra. If doubt exists, a soft rubber catheter should be passed and a specimen of urine obtained. Great care must be taken to avoid infection, and the catheterisation is best done in the operating theatre, rather than in the casualty department. On no account should the patient be told to "see if he can pass water," as in the presence of a tear extravasation of urine will result.

(*b*) *Rupture of the bladder.* Intra- or extra-peritoneal rupture may occur, especially if the bladder is full at the time of injury.

Suggestive signs of intra-peritoneal rupture are severe shock and abdominal dullness and rigidity, together with the non-passage of urine in spite of fluids being taken by the mouth. A small quantity of blood-stained urine may be obtained by catheter (see also Vol. II, page 2887).

(*c*) *Injuries to the rectum* are rare, and no case occurred in the series of 100 quoted. Complete investigations of a case of pelvic injury should, however, include a rectal examination. When the sacrum or coccyx is injured, it may be possible to palpate or replace a fracture by this means.

(*d*) *Injury to the pelvic veins* may result in thrombosis. Occasionally

pulmonary embolism has occurred, and in other cases the thrombosis has extended to the femoral vein, the resulting œdema of the leg proving a serious disability.

(e) *The sacral nerves* emerge through foramina considerably larger than the diameter of the nerve trunks. Hence, pressure from displaced fractures or by callus is rare, but sciatic pain as a sequela of pelvic injury must be borne in mind.

Treatment of Uncomplicated Cases.

The treatment of shock should be the first consideration.

In the majority of cases, displacement is negligible and all that is necessary is to support the pelvis with a firm binder. The patient should be nursed on a divided mattress, and kept in bed for a minimum of six weeks. Instead of a binder, a well-moulded pair of "plaster knickers" may be applied, including the pelvis and both thighs as far as the knee. A plaster bed can be used, extending from the middle of the back to the knees.

If one side of the pelvis is displaced upon the other, the movement is usually in an upward direction, owing to the pull of the abdominal and psoas muscles. Should this happen, an attempt may be made to overcome the deformity by continuous traction upon the leg, after the manner of Hoke's traction for dislocation of the sacro-iliac joint. The patient may be allowed up in his plaster after six weeks, and may attempt to walk with the help of crutches. A period of three months will probably be necessary before the plaster and crutches can be discarded completely.

When fractures of the pelvis are complicated by injury to the urethra, bladder, rectum or other viscera, primary treatment is directed to the visceral complication. A prompt diagnosis of the complication is essential for a satisfactory recovery, and neglect of the fracture of the pelvis until the visceral lesion is dealt with seldom affects the prognosis of the fracture.

The *prognosis* after simple fracture is satisfactory but progress is slow. There is commonly complaint of a feeling of insecurity about the pelvis, particularly when walking.

Treatment of urethral and bladder injury is described in Vol. II, pages 3066 and 2888.

Acetabulum.

(1) Fracture of the rim.

(2) Fracture of the floor (central dislocation of the hip joint).

(1) Fracture of the rim of the acetabulum is usually associated with dislocation of the hip joint. The postero-superior portion of the rim is

separated upwards. It is recognisable by the fact that reduction of the dislocation is easy, but its retention is difficult. There should be no mistake about the diagnosis from the X-ray pictures.

Treatment consists of reduction of the dislocation under an anæsthetic and of fixation of the thigh in a position of full abduction.

In a young patient a plaster spica should be employed, extending from above the waist down to and including the foot on the affected side. Such an appliance is not suitable for an elderly or heavily-built patient, who should be placed on a divided mattress, and strapping extension applied to the limb and to an extension pulley. Some degree of tilting of the pelvis can be prevented by the use of a flannel bandage applied as a pelvic band round the sound groin and tied above to the opposite corner of the bed.

In young patients, if the fractured portion includes a considerable area of the roof of the acetabulum, the fractured portion of bone should be fixed in place by an open operation.

(2) A direct blow applied to the region of the great trochanter may drive the head of the femur into or through the floor of the acetabulum so that the acetabulum becomes comminuted.

Treatment. When the floor is fractured without inward displacement of the head of the femur, the patient should be put to bed and a weight extension applied to the limb for six weeks. Subsequently, a weight-bearing caliper should be worn for another six weeks. Inefficient treatment will be followed by painful ankylosis of the hip. Even after the best treatment, a painful hip with limitation of movement will sometimes occur. In the more severe cases, arthrodesis may be required.

When the femoral head is driven through the floor of the acetabulum, an attempt must be made to disengage it under a general anæsthetic. Fixation is then required in a position of 20 degrees flexion, with slight external rotation and abduction so that, should ankylosis occur, the ultimate function of the limb will be the best possible.

Failure to reduce the head by manipulative traction should be followed by the insertion of a screw into the great trochanter and the application of traction. An open reduction involves an intra-pelvic operation and leaves a condition of the hip which is painful and will be followed by secondary arthritis. These fractures are serious injuries; considerable limitation of movement is to be expected; pain is a frequent sequela and arthritis occurs later.

Note. In viewing skiagrams of elderly patients, the floor of the acetabulum may appear to have sunk into the pelvis, the femoral head appearing deeply placed. The condition may be bilateral and is one of "protrusio acetabuli," not necessarily associated with a past injury.

FEMUR

Upper End of Femur

This region includes the head, neck and trochanters. Various classifications are in use, but the simplest would appear to be that based upon the anatomical site of the fracture. Hence we may speak of capital: sub-capital; cervical; basal; inter- or per-trochanteric; and sub-trochanteric fractures.

The older classification into intra- and extra-capsular fractures has no particular advantage, and leads to much confusion as to the exact type of the fracture. Strictly speaking, intra-capsular fractures should

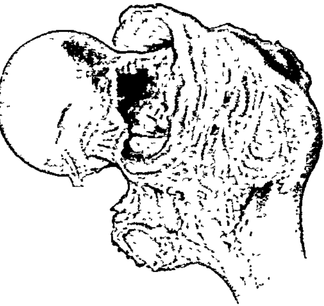

Fig. 2398.—Sub-capital fracture of neck of femur (intra-capsular). (Museum, King's College Hospital.)

include all those occurring above the anterior intertrochanteric line, while extra-capsular should refer to fractures of the intertrochanteric variety.

For purposes of treatment it is sufficient to recognise *three varieties:*

(1) *Sub-capital fracture* (fig. 2398). This is the commonest variety of cervical fracture.

(2) *Basal fracture of the neck* (fig. 2399).

(3) *Inter- or per-trochanteric fracture* (fig. 2400).

(The sub-trochanteric fracture is really a fracture of the upper end of the shaft, and will be considered under the appropriate section, while fracture of the head itself is a rarity.)

The recognition of these three types is of the utmost importance, both from the point of view of treatment and of prognosis. Good

skiagrams are essential and, if possible, a lateral as well as an antero-posterior view should be taken.

Method of taking X-ray pictures of the Neck of the Femur

(*a*) *Ordinary antero-posterior view.* (i) With leg rolled in; (ii) With leg rolled out.

(*b*) *Lateral view.* (i) With legs widely abducted, the film is held parallel with the neck, the edge of the casette being pressed firmly into the soft parts below the costal margins. The X-ray tube is situated in the region of the foot of the sound leg. (ii) The patient is placed in the lithotomy position. The film is held as before, and the tube is located near the perineum of the patient.

The taking of lateral skiagrams in this region will necessitate the use of shock-proof apparatus, and some form of anæsthesia will be necessary to place the limb

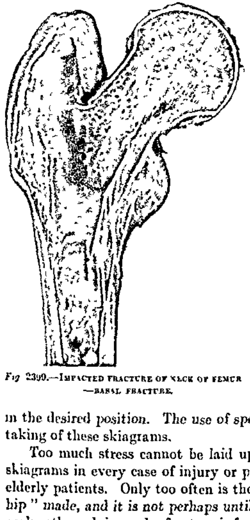

Fig 2399.—Impacted fracture of neck of femur —basal fracture.

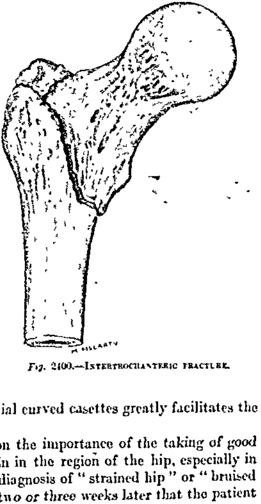

Fig. 2400.—Intertrochanteric fracture.

in the desired position. The use of special curved casettes greatly facilitates the taking of these skiagrams.

Too much stress cannot be laid upon the importance of the taking of good skiagrams in every case of injury or pain in the region of the hip, especially in elderly patients. Only too often is the diagnosis of "strained hip" or "bruised hip" made, and it is not perhaps until two or three weeks later that the patient seeks other advice and a fracture is found.

The type of fracture most likely to be "missed" on clinical examination is the *impacted fracture*, in which there is little or no shortening and no outward rotation of the leg, and on which the patient has possibly walked for some days after the accident.

The possibility of a *pathological fracture*, due to malignant disease, must always be borne in mind; when secondary carcinomatous deposits are the cause, they are usually situated in the sub-trochanteric region rather than in the neck.

General considerations. It should be realised that of the three types mentioned, basal fracture of the neck and intertrochanteric fracture usually unite readily by bone.

Basal fractures are often impacted into the region of the trochanters without much deformity or shortening, whereas in the intertrochanteric variety considerable separation of the fragments, with shortening and coxa vara, is the rule. The treatment of these types is discussed in a later section.

Trans-cervical Fractures

According to recent literature these constitute only one-third of the fractures of the upper end of the femur, the other two-thirds being fractures in the region of the trochanters.

They may be sub-divided into two types:

(1) *Abduction* (Valgus). The angulation of the neck is open upwards and forwards. The fracture is usually impacted. Bony union

Fig. 2401.—Skiagram of fracture of neck of femur, showing coxa vara and rotation of the head.

occurs readily if the fracture is immobilised in a short plaster spica for three months, the patient being allowed to walk after six weeks. The fracture should never be disimpacted.

(2) *Adduction* (Varus). (Fig. 2401.) The angulation of the neck is open backwards and inwards. The head is rotated backwards and the

leg rolled out, so that the fractured surfaces of the neck look forward. Separation of the fragments is the rule, and non-union will occur unless adequate steps are taken to immobilise both the upper and lower fragments in relation to one another.

Reasons for non-union in abduction fractures of the neck of the femur:

(1) The fragments are separated.

(2) The blood supply to the "capital fragment" runs up the neck from vessels supplied by the capsule of the joint. When fracture occurs, both capsule and blood-vessels are torn. In sub-capital fractures the head may become completely avascular.

(3) Even if adequate reduction is obtained by manipulation, movement between the fragments will repeatedly destroy newly-formed vessels, and non-union will result. Torsional or rotatory movements of the head are impossible to control by any form of external splintage.

(4) The usual reasons given for non-union—such as senility, poor blood supply to the neck as a whole, and the presence of synovial fluid—do not appear to carry weight in the light of recent research. Inadequate treatment, i.e. incomplete immobilisation, has been the reason for past failures in this field.

In order to obtain osseous union in this type of fracture the following criteria must be aimed at:

(1) Good alignment and apposition of the head and neck, obtained by manipulative reduction.

(2) Complete fixation of the fragments, relative to one another. This can only be accomplished by operative means.

(3) Relief from weight-bearing for a sufficient time for bony union to take place. Opinions as to the length of this period vary. (Böhler advises rest in bed for 3–4 weeks, followed by walking in a plaster-cast, which is removed in 12 weeks.) When in doubt it is better to err on the side of caution and to check the progress of union by X-ray photographs. In many cases it may be wise to provide the patient with a weight-bearing caliper for several months, even after union appears to be firm on X-ray examination.

Age Incidence and Choice of Treatment.

Whatever form of treatment is adopted, the age of the patient will have an important bearing upon the results. In a survey of 311 cases by Stebbing in 1927, the average age both for cervical and trochanteric fractures was 69 years. These cases were treated by extension or abduction in plaster. In a more recent series of 100 cases by Watson Jones (1936) the average age, excluding the trochanteric region, was found to be 58·5 years.

In deciding what form of treatment to adopt, age, type of fracture, and general condition of the patient must be considered. If the patient with an abducted fracture is unsuitable for operative treatment, then immobilisation in plaster-of-Paris or by some other method may be suitable.

Treatment of Trans-cervical Fractures.

Adduction type. The diagnosis having been made, both by clinical and X-ray observations, the method of choice is undoubtedly that of operative fixation of the fracture by the Smith-Petersen nail. The virtue of the nail lies in the fact that it is provided with three flanges which firmly engage the femoral head and make rotatory movements impossible. Wires, screws, and bone pegs or grafts are all open to the objection that, being rounded, they cannot grip the femoral head. Bone grafts have the additional disadvantage of liability to absorption or fracture before bony union is complete. The best type of nail has a central canal, so that it may be threaded over a guide wire previously inserted.

When to operate is an important point. There is no extreme urgency, and probably the best plan is to put the patient to bed, with a weight extension on the leg, for about a week, and then to perform the operation. During this time, initial swelling will have subsided, and there will be ample opportunity for a detailed investigation of the general health. It should be emphatically stated that, if operative treatment be decided upon, the operation should *not* be undertaken lightly, and then only by one versed in the technique. It is beset with difficulties and not a few dangers.

Two methods of insertion of the nail are in use:

(1) By open operation ; or

(2) By "blind" insertion.

(1) *Open Operation.*

(*a*) The fracture is first reduced by traction ; the femoral neck is then exposed and the accuracy of reduction checked. The guide is inserted under direct vision, and its position subsequently checked by X-ray examination. The nail is then inserted.

(*b*) The femoral neck is exposed and the fracture reduced by traction under direct vision. Guide wire and nail are inserted by direct vision without the help of X-ray photographs.

(2) "*Blind*" *Insertion.*

In this method, the fracture is reduced by traction and the guide inserted through a small incision below the great trochanter. The accuracy of insertion is checked by skiagrams before insertion of the nail.

Accurate insertion is facilitated by the use of: (*a*) Mechanical appliances (Hey Groves, Eric Lloyd, and others); and (*b*) Bony points of the skeleton (Johansson).

Of the two methods, there can be no doubt that insertion of the guide wire by open reduction, with free exposure of the site of the fracture, is the method of choice. This is carried out as follows:

(*a*) The fracture is visualised, and the accuracy of reduction is checked.

(*b*) The guide wire is inserted under direct vision.

(*c*) Elaborate instruments for controlling the insertion of the guide wire are unnecessary.

(*d*) Few arithmetical and no geometrical calculations are required.

(*e*) It is possible to obtain accurate placing of the guide wire (and of the nail) without the use of X-ray examination in the operating theatre, although a skiagram check is an added advantage. If skiagrams are dispensed with during the operation, operating time may be reduced from the necessary 1½–2 hours to within 1 hour. On the other hand, it must be admitted that the operation is one of considerable magnitude, involving extensive dissection, and is open to the usual operative risks.

Shock, however, does not appear to be greatly increased when the "open" method is used, and the time saved more than compensates for the added exposure and loss of blood.

Both methods will now be described in some detail:

(1) *Insertion by Open Operation (Modified Smith-Petersen).*

(*a*) *Anæsthetic.* The blood-pressure should be taken, and if not abnormally low a spinal anæsthetic (percaine) should be given. Conditions will be more satisfactory for patient and operator if sufficient gas and oxygen to produce unconsciousness be administered. Should spinal anæsthesia be contra-indicated, gas-oxygen-ether is probably the best substitute.

(*b*) *Operating table.* Some form provided with a perineal post against which traction can be made is desirable. Screw-traction appliances to the feet are a great advantage, but not essential, as in their absence the foot can be controlled and traction applied by an assistant.

(*c*) *Choice of nail.* Before operating, it is necessary to have an X-ray picture of the *normal* hip of the patient, together with a Smith-Petersen nail, of known length, or a steel measure, on the same film.

FIG. 2102.—HOLLOW SMITH PETERSEN PIN.

It is then easy to decide what length of nail will be required, and errors due to distortion are avoided.

(*d*) *Incisions:* (i) Smith-Petersen (see fig. 2344 B); or (ii) Lateral approach (fig. 2403).

Occasionally the large flap turned down in the Smith-Petersen

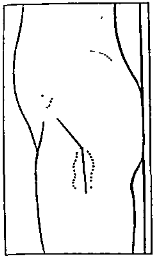

Fig. 2403.—Lateral approach to the neck of the femur.

incision may slough. A lateral approach is advocated to avoid this danger (Watson Jones).

If the Smith-Petersen approach is employed, the rectus femoris and tensor fasciæ femoris are retracted outwards, and the capsule of the joint is divided in a longitudinal direction.

If the *lateral* approach is used, the tensor fasciæ femoris is pulled forwards and the gluteus medius partially detached from its insertion

Fig. 2404.—Hollow punch to fit over guide pin for driving nail home.

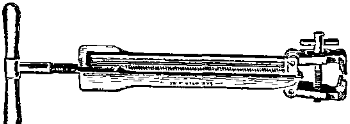

Fig. 2405.—Extractor for removal of Smith Petersen pin.

into the great trochanter and retracted backwards. The capsule is incised along the intertrochanteric line as well as longitudinally, and the triangular opening thus made gives a good view of the neck.

Care should be taken of the exposed muscles by repeated applications of hot cloths.

(*e*) The leg is now rolled out, thus exposing the fractured surfaces. A guide wire is inserted in the centre of the femoral shaft, $\frac{1}{2}$–$\frac{3}{4}$ inch below the base of the great trochanter, and drilled into the bone with an ordinary Kirschner wire drill. (If a rigid pin is used as guide an "awl" handle may be employed.) The guide is made to appear in the centre of the fractured surface of the neck.

(*f*) *Reduction* is now obtained by traction on the leg in the direct line of the body. No abduction should be used at this stage, but slight flexion and internal rotation may help in accurate reduction. Accuracy of reduction is controlled by direct vision, when complete abduction will "lock" the fragments together.

The guide wire is then driven into the proximal fragment for the required distance. (The length of guide necessary may be measured from the X-ray picture of the normal hip, taking into account the distortion which is always present in X-ray films.) It is important that the articular cartilage of the head should not be pierced. At this stage many operators prefer to have the position of the guide wire checked by antero-posterior and lateral skiagrams. If this is done, great care must be taken not to introduce sepsis into the wound. The film casette must be wrapped in sterile towels and the wound itself adequately covered.

Having decided, by visual or radiological control, that the fracture is perfectly reduced and the guide inserted correctly, the nail is now threaded over the guide and hammered home with the special hollow punch. Care must be taken that the guide is not driven into the acetabulum during this process.

The guide is removed and a further film taken. If the position of the nail is unsatisfactory it must be extracted with the special extractor and re-inserted. Accuracy of reduction and firm fixation does away with the necessity of impaction by a hammer.

The wound is closed, and it may be advisable to drain it for twenty-four hours, as the large hæmatoma which sometimes forms is liable to become infected.

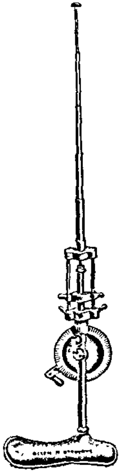

Fig. 2406.—Telescopic introducer for guide wires when used alternatively to rigid guide pin.

It is then easy to decide what length of nail will be required, and errors due to distortion are avoided.

(*d*) *Incisions:* (i) Smith-Petersen (see fig. 2344 B); or (ii) Lateral approach (fig. 2403).
